Abstract

In the framework of Euclidean QCD on a torus, we study the spectrum of the Dirac operator through inverse moments of its eigenvalues, averaged over topological sets of gluonic configurations. The large-volume dependence of these sums is related to chiral order parameters. We sketch how these results may be applied to lattice simulations in order to investigate the chiral phase transitions occurring when N_f increases. In particular, we demonstrate how Dirac inverse moments at different volumes could be compared to detect in a clean way the phase transition triggered by the suppression of the quark condensate and by the enhancement of the Zweig-rule violation in the vacuum channel.

I. INTRODUCTION

Understanding the Spontaneous Breakdown of Chiral Symmetry (SBχS) remains one of the most challenging non-perturbative problems of QCD. Forthcoming experiments [1–3] should reveal some of its features, at least in the non-strange sector in which the effective number of light quark flavours is minimal ($N_f = 2$). It is generally expected that if N_f increases (keeping the number of colours N_c fixed), the theory meets phase transitions and the chiral symmetry is eventually restored. The argument is originally based on properties of the QCD β-function in perturbation theory. The well-known statement of the "end of asymptotic freedom" for $N_f \geq 11N_c/2$ [4] has been further completed by the analysis of the so-called "conformal window" [5] suggesting a restoration of chiral symmetry for lower N_f, such as $N_f \sim 10$ (for $N_c = 3$) [6]. Less perturbative and more model-dependent investigations, based on a gap equation [7] or on a "liquid instanton model" [8], also indicate that a chiral phase transition could occur for N_f substantially below $11N_c/2$.

It is important to understand, at least qualitatively, the non-perturbative origin of the suppression of chiral order parameters for an increasing N_f. We have recently argued [9] that such a suppression might result from a paramagnetic effect of light (massless) quark loops [10], i.e. it could be due to "sea quarks" and, consequently, it could escape a detection in quenched lattice simulations, or in any other approach neglecting the fermion determinant. An appropriate framework to develop these ideas and to ask precise questions is the formulation of QCD in an Euclidean box $L \times L \times L \times L$, with periodic (antiperiodic) boundary conditions for gluon (fermion) fields, up to a gauge transformation. In this framework, the SBχS pattern is reflected by the dynamics of lowest eigenvalues of the Dirac operator:

$$H[G] = \gamma_\mu(\partial_\mu + iG_\mu). \tag{1.1}$$

This Hermitian operator has a symmetric spectrum with respect to zero: $\{H, \gamma_5\} = 0$. Positive eigenvalues λ_n are labeled in ascending order by a positive integer (one further denotes $\lambda_{-n} = -\lambda_n$ and $\phi_{-n} = \gamma_5\phi_n$ for the corresponding eigenvectors). SBχS is related to a particularly dense accumulation of eigenvalues around zero [11–13,21]. Models of such an accumulation in terms of random matrices [14] or instantons [15] have been proposed. Some chiral order parameters are entirely dominated by the infrared extremity of the spectrum of the Dirac operator (1.1). This makes them particularly sensitive to the statistical weight given to smallest Dirac eigenvalues in the functional integral, which is suppressed in the massless limit by the N_f-th power of the fermion determinant. A good example is the quark condensate, defined by:

$$\Sigma(N_f) = -\lim_{m_1,m_2,\ldots m_{N_f}\to 0} \langle 0|\bar{u}u|0\rangle, \tag{1.2}$$

where $m_1 \ldots m_{N_f}$ denote the N_f lightest quark masses and u represents the lightest quark field. $\Sigma(N_f)$ receives exclusive contributions from the smallest Dirac eigenvalues that behave in average as $1/L^4$, and it is consequently expected to be the most sensitive order parameter to the variation of N_f and to a phase transition. Other order parameters are less sensitive, like $F^2(N_f)$, defined as the $\mathrm{SU}_L(N_f)\times\mathrm{SU}_R(N_f)$ limit of the coupling of the Goldstone bosons to the axial current:

$$F^2(N_f) = \lim_{m_1, m_2, \ldots m_{N_f} \to 0} F_\pi^2. \tag{1.3}$$

$F^2(N_f)$ may be non-zero due to Dirac eigenvalues accumulating as $1/L^2$ [13]. For this reason, $F^2(N_f)$ should exhibit a weaker N_f-dependence than $\Sigma(N_f)$. Finally, observables with no particular sensitivity to the infrared edge of the Dirac spectrum (ρ-mass, string tension, etc…) have no reason to be strongly affected by the fermion determinant and by the N_f-dependence.

Let us first consider the thermodynamical limit and denote by $n_{\text{crit}}(N_c)$ the critical value of N_f at which the first chiral phase transition takes place. Just below $n_{\text{crit}}(N_c)$, the order parameter $\Sigma(N_f)$ drops out, whereas its fluctuations may be expected to become important. We have shown [9] that the latter would manifest itself by an enhancement of the Zweig-rule violation just in the vacuum channel $J^{PC} = 0^{++}$. An important Zweig-rule violation is precisely observed in the scalar channel [16], and nowhere else (with the exception of the pseudoscalar channel driven by the axial anomaly). Whilst the signature of a nearby phase transition is rather clear just below $n_{\text{crit}}(N_c)$, it is more speculative and ambiguous above the critical point. First, above $n_{\text{crit}}(N_c)$, colour might still be confined (confinement has no obvious relation to small Dirac eigenvalues). Second, despite $\Sigma(N_f) = 0$, the chiral symmetry need not be completely restored. The Goldstone bosons coupling to conserved axial currents with the strength $F(N_f)$ might survive to the N_f-induced phase transition. This is reflected by the possibility that the N_f-sensitivity and suppression of the order parameter $F^2(N_f)$ might be considerably weaker than in the case of the quark condensate [13]. Of course, this is a highly non-trivial possibility, which presumably depends on the existence of a non-perturbative fixed point in the renormalization group flow[1]. Here, we take as a working hypothesis that above $n_{\text{crit}}(N_c)$, a partial SBχS still occurs, due to $F^2(N_f) \neq 0$. The results of our paper allow, in particular, to test this hypothesis.

The central question remains how far is $n_{\text{crit}}(N_c)$ (for $N_c = 3$) from the real world, in which the number of light quarks hardly exceeds $N_f = 2 - 3$. Some recent investigations actually indicate that $n_{\text{crit}}(3)$ could be rather small, and/or that the real world could already feel the influence of a nearby phase transition. First, some lattice simulations with dynamical fermions observe a strong N_f-dependence of SBχS signals for N_f as low as 4-6 [18,19]. Second, a method based on a well-convergent chiral sum rule has been proposed, which allows to study phenomenologically the variation of $\Sigma(N_f)$ for small N_f [20]. It has been found that existing experimental information on the Zweig-rule violation in the scalar channel leads to a large reduction of $\Sigma(N_f)$ already between $N_f = 2$ and $N_f = 3$.

The purpose of this paper is to analyze in a model-independent way how N_f-induced chiral phase transitions manifest themselves in the finite-volume partition function. In particular, we shall investigate the volume dependence of the inverse spectral moments of the Dirac operator (1.1):

---

[1] If one sticks to cut-off-dependent bare quantities, it is possible to argue that $\Sigma = 0$ would imply $F = 0$, i.e. the full symmetry restoration [17]. This argument is however based on an inequality for which it is by no means obvious that it survives in the full renormalized theory.

$$\sigma_k = \sum_{n>0} \frac{1}{(\lambda_n[G])^k}, \tag{1.4}$$

averaged over topological sets of gluonic configurations. For $N_f \ll n_{\mathrm{crit}}(N_c)$, the leading large-volume behaviour of such inverse moments has been worked out in details by Leutwyler and Smilga [21]. In order to investigate how this result is modified in the vicinity and above $n_{\mathrm{crit}}(N_c)$, we rely on the basic observations and methods of Ref. [21]. For large sizes of the box ($\Lambda_H L \gg 1$ with $\Lambda_H \sim 1$ Gev), heavy excitations are exponentially suppressed in the partition function, which is then dominated by the lightest states, the pseudo-Goldstone bosons of SBχS. This leads to an effective description in terms of the Chiral Perturbation Theory (χPT) [22,23], and it can be matched with QCD, yielding the desired information concerning the infrared properties of the Dirac spectrum. Moreover, the effective Lagrangian is identical to its infinite-volume counterpart, provided that periodic boundary conditions are used [24].

If N_f lies far below $n_{\mathrm{crit}}(N_c)$, the quark condensate is large and σ_k behaves at large (but finite) volumes according to the asymptotic behaviour derived by Leutwyler and Smilga [21], using Standard χPT [22]. Above $n_{\mathrm{crit}}(N_c)$, the quark condensate vanishes, and the previous analysis cannot be applied. However, if chiral symmetry is still partially broken, the matching with χPT remains possible and it leads to a clear-cut change in the large-volume behaviour of σ_k : expressed through their inverse moments, the average behaviour of the lowest eigenvalues for $L \to \infty$ should turn from $1/L^4$ ($\langle \bar{q}q \rangle \neq 0$) into $1/L^2$ ($\langle \bar{q}q \rangle = 0$) [13]. When we approach the critical point with N_f near but under $n_{\mathrm{crit}}(N_c)$, significant discrepancies from the asymptotic limit $L \to \infty$ could be seen for large but finite boxes. The latter should then be analyzed using the framework of Generalized χPT [23,35]. We have clearly in mind the possibility to use unquenched lattice simulations, varying N_f and (finite) lattice size L to eventually detect chiral phase transitions, through the volume dependence of inverse moments (1.4).

This article is organized as follows. In Sec. 2, we briefly review features of Euclidean QCD and of the effective theory on a torus. Sec. 3 explains how both theories are matched to derive the original form of Leutwyler-Smilga sum rules below $n_{\mathrm{crit}}(N_c)$, before analyzing how they are modified in the phase where the quark condensate vanishes. In Sec. 4, we discuss the approach to the critical point, where a competition between a small quark condensate and higher order contributions leads to sizeable computable finite-volume effects. Sec. 5 is devoted to the computation of the next-to-leading-order corrections to the sum rules. We discuss in Sec. 6 how to obtain from the inverse moments an unambiguous signal indicating that N_f approaches $n_{\mathrm{crit}}(N_c)$, and we discuss the interest of lattice simulations in this framework. Sec. 7 summarizes the main results of this work.

II. SMALL MASS AND LARGE VOLUME EXPANSION OF THE PARTITION FUNCTION

A. Euclidean QCD on a torus

The Euclidean[2] QCD Lagrangian for N_f light quarks reads:

$$\mathcal{L}^{(N_f)} = \frac{1}{4g^2} G^a_{\mu\nu} G^a_{\mu\nu} - i\theta\nu - i\bar{q}\not{D}q + \bar{q}\tilde{M}q, \tag{2.1}$$

with the winding number density:

$$\nu(x) = \frac{1}{32\pi^2} G^a_{\mu\nu}(x) \tilde{G}^a_{\mu\nu}(x), \tag{2.2}$$

and the vacuum angle θ [25]. The quark mass matrix $\tilde{M}$ is of the form:

$$\tilde{M} = \frac{1}{2}(1-\gamma_5)M + \frac{1}{2}(1+\gamma_5)M^\dagger, \tag{2.3}$$

where M is a $N_f \times N_f$ complex matrix, diagonal in a suitable quark basis with positive real eigenvalues.

We consider the partition function of this Euclidean theory in a finite box $L \times L \times L \times L$, large enough to neglect safely the heavy quarks:

$$Z^\theta(N_f) = \mathcal{C} \int [dG] \int [d\bar{\psi}][d\psi] \exp\left(- \int_V d^4x\ \mathcal{L}^{(N_f)} \right), \tag{2.4}$$

where $\mathcal{C}$ is a normalization constant, which may depend on the volume, but not on the mass matrix.

We impose boundary conditions on the fields, by viewing the box as a torus and identifying x_μ and $x_\mu + n_\mu L$ (with n_μ integers): the gluon fields have to be periodic and the quark fields antiperiodic in the four directions, up to a gauge transformation. The gauge fields are classified with respect to their winding number $\nu = \int_V dx\ \nu(x)$, which is a topologically invariant integer (related to the gauge transformation defining the periodicity of the fields on the torus). The index theorem asserts that ν is the difference between the number of left-handed and right-handed Dirac eigenvectors with a vanishing eigenvalue.

The Dirac eigenvalues satisfy a uniform bound [11]:

$$|\lambda_n[G]| < C \frac{n^{1/d}}{L} \equiv \omega_n. \tag{2.5}$$

This bound means essentially that an external gauge field lowers the eigenvalues of the free field theory [10]. It involves a coefficient C, depending only on the geometry of the space-time manifold, but neither on G, n or $V = L^d$. The partition function Z can be decomposed in Fourier modes over the winding number:

---

[2] In this paper, all the expressions are written in the Euclidean metric, unless explicitly stated.

$$Z^\theta(N_f)=\sum_{\nu=-\infty}^{\infty} e^{i\nu\theta} Z_\nu(N_f). \tag{2.6}$$

Each projection of positive winding number ν is:

$$Z_\nu(N_f)=\mathcal{C}\int_\nu [dG] e^{-S_{\mathrm{YM}}[G]} \det(-i\not{D}+\tilde{M}) \tag{2.7}$$

$$=\mathcal{C}\int_\nu [dG] e^{-S_{\mathrm{YM}}[G]} (\det{}_f M)^\nu \prod_n{}' \left[\frac{\det_f(\lambda_n^2+MM^\dagger)}{(\omega_n^2+\mu^2)^{N_f}}\right], \tag{2.8}$$

$\int_\nu$ denotes the integration over the set of the gluonic configurations with a fixed winding number ν, and S_{YM} is the pure gluonic action. $\det_f M$ is the determinant of the $N_f \times N_f$ quark mass matrix (it is replaced by $(\det_f M^\dagger)^{-\nu}$ for $\nu \le 0$). The primed product includes only the strictly positive eigenvalues: its denominator involves the Vafa-Witten bound ω_n of Eq. (2.5) and a reference mass scale μ larger than any light quark mass. It represents a convenient normalization of the determinant, such that each factor of the primed product is lower than 1 when the quark masses tend to zero. This normalization does not affect any observable. We check that the quark mass matrix and the vacuum angle arise in the partition function through the product $M\exp(i\theta/N_f)$, consistently with the anomalous Ward identity for the singlet axial-vector current.

The partition function for a fixed positive winding number is:

$$\begin{aligned} Z_\nu(N_f)=&\mathcal{C}\int_\nu [dG] e^{-S_{\mathrm{YM}}[G]} (\det_f M)^\nu \\ &\times\left(\prod_n{}' \frac{\lambda_n^2}{\omega_n^2+\mu^2}\right)^{N_f} \exp\left[\left\langle \sum_n{}' \log\left(1+\frac{MM^\dagger}{\lambda_n^2}\right)\right\rangle\right], \end{aligned} \tag{2.9}$$

where $\langle\rangle$ denotes the trace over flavours. Provided that the partition function is regularized, we can expand the logarithm for small masses (compared to the size of the box):

$$\begin{aligned} Z_\nu(N_f)=&\mathcal{C}\int_\nu [dG] e^{-S_{\mathrm{YM}}[G]} (\det_f M)^\nu \left(\prod_n{}' \frac{\lambda_n^2}{\omega_n^2+\mu^2}\right)^{N_f} \\ &\times\exp\left[\langle M^\dagger M\rangle\sigma_2-\frac{1}{2}\langle (M^\dagger M)^2\rangle\sigma_4+O(M^6)\right] \end{aligned} \tag{2.10}$$

$$\begin{aligned} =&\mathcal{C}'_\nu (\det_f M)^\nu \left[1+\langle M^\dagger M\rangle \langle\langle\sigma_2\rangle\rangle_\nu^{(N_f)} - \frac{1}{2}\langle (M^\dagger M)^2\rangle \langle\langle\sigma_4\rangle\rangle_\nu^{(N_f)}\right. \\ &\left.+\frac{1}{2}\langle M^\dagger M\rangle^2 \langle\langle(\sigma_2)^2\rangle\rangle_\nu^{(N_f)} + O(M^6)\right]. \end{aligned} \tag{2.11}$$

The inverse moments are defined for each gluonic configuration as: $\sigma_k=\sum_n{}' 1/\lambda_n^k$. The normalization factor $\mathcal{C}'_\nu$ is independent of the quark mass matrix:

$$\mathcal{C}'_\nu=\mathcal{C}\int_\nu [dG] e^{-S_{\mathrm{YM}}[G]} \left(\prod{}'_n \frac{\lambda_n^2}{\omega_n^2+\mu^2}\right)^{N_f}. \tag{2.12}$$

The average over gluonic configurations with a given winding number is defined by

$$\langle\!\langle W \rangle\!\rangle_\nu^{(N_f)} = \frac{\int_\nu [dG] e^{-S_{\rm YM}[G]} \left(\prod_n' \lambda_n^2\right)^{N_f} \; W}{\int_\nu [dG] e^{-S_{\rm YM}[G]} \left(\prod_n' \lambda_n^2\right)^{N_f}}. \tag{2.13}$$

where the denominator is a normalization factor, $\langle\!\langle 1 \rangle\!\rangle_\nu = 1$. In Eq. (2.11), this average is applied to inverse moments σ_k that are particularly sensitive to the infrared tail of the Dirac spectrum. On the other hand, $\langle\!\langle \rangle\!\rangle_\nu^{(N_f)}$ includes a product over eigenvalues, which should suppress the statistical weight of the lowest eigenvalues when the number N_f of massless flavours increases. The averaged inverse moments in the exponential of Eq. (2.11) could therefore exhibit a strong dependence on N_f.

(2.10) contains several sources of divergences. Let us first consider the gluonic configuration as a fixed external field. In the fermion sector, sums over the Dirac spectrum may diverge because of its ultraviolet tail. For $\lambda \to \infty$, the number of eigenvalues in $[\lambda, \lambda + \Delta\lambda]$ is given by the free theory:

$$\Delta n = \frac{N_C}{4\pi^2} V |\lambda|^3 \Delta\lambda. \tag{2.14}$$

The expected ultraviolet divergences of the inverse moments have therefore to be subtracted. We can write:

$$\sigma_2 = \tilde\sigma_2 + D_2^{(N_f)}, \qquad \sigma_4 = \tilde\sigma_4 + D_4^{(N_f)}, \tag{2.15}$$

where the divergent part is included in D, and $\tilde\sigma$ is finite. For instance, we can choose an ultraviolet cutoff Λ and define the integer K such that $\omega_K = \Lambda$. The regularized inverse moments then read:

$$\tilde\sigma_k = \sum_{n=1}^{K} \frac{1}{(\lambda_n)^k}, \tag{2.16}$$

and the divergent parts behave (at the leading order of the volume) like:

$$D_2^{(N_f)} \sim V\Lambda^2, \qquad D_4^{(N_f)} \sim V \ln \Lambda. \tag{2.17}$$

These short-distance contributions are the same for all winding-number sectors. If we perform this splitting in Eq. (2.10), we obtain the regularized partition function $\tilde Z_\nu$ involving the inverse moments $\tilde\sigma$, multiplied by an exponential factor with divergent counterterms which contribute only to the vacuum energy:

$$Z_\nu(N_f) = \tilde Z_\nu(N_f) \exp\left[D_2^{(N_f)} \langle M^\dagger M \rangle - \frac{1}{2} D_4^{(N_f)} \langle (M^\dagger M)^2 \rangle \right]. \tag{2.18}$$

Secondly, the product over the eigenvalues in the fermion determinant of Eq. (2.13) needs a regularization already for a fixed gluonic configuration. Nevertheless, for observables dominated by the lowest Dirac eigenvalues, we expect less sensitivity to the ultraviolet tail of the determinant. If we split the product over eigenvalues into ultraviolet and infrared parts [9,32]:

$$\Delta = \Delta_{\mathrm{IR}}\Delta_{\mathrm{UV}}, \qquad \Delta_{\mathrm{IR}} = \prod_{n=1}^{K} \left(\frac{\lambda_n^2}{\omega_n^2 + \mu^2} \right)^{N_f}, \tag{2.19}$$

we can expect the gluonic average of the inverse moments to depend essentially on Δ_{IR}, with a weak sensitivity on Λ.

Up to now, the gauge configuration was viewed as an external field, but the integration over the gluonic fields leads to a third series of divergences. Fortunately, their regularization is rather disconnected from the fermion sector [26] (for instance, the cut-off may be chosen independently of Λ). For the purpose of this paper, it is sufficient to stick to a multiplicative renormalization of the mass matrix and the Dirac eigenvalues,

$$M \to Z_m M, \qquad \lambda_n \to Z_m \lambda_n, \tag{2.20}$$

inducing a multiplicative renormalization for $\langle\langle \sigma_k \rangle\rangle_\nu^{(N_f)}$. We shall only consider homogeneous quantities, like ratios of inverse moments with the same degree of homogeneity in λ: the problem of the renormalization in the gluonic sector is therefore discarded in the rest of this article.

B. Effective Lagrangian

For large volumes, the massive states are exponentially suppressed. The partition function is therefore dominated by the $N_f^2 - 1$ pseudo-Goldstone bosons resulting from the Spontaneous Breakdown of Chiral Symmetry and described at low energies by the Chiral Perturbation Theory (χPT). The effective Lagrangian for Goldstone bosons is written as a double expansion in powers of the momenta p and of the quark masses m:

$$\mathcal{L}_{\mathrm{eff}} = \sum_{k,l} \mathcal{L}_{(k,l)}, \tag{2.21}$$

where $\mathcal{L}_{(k,l)}$ gathers all terms contributing like $p^k m^l$. In Euclidean QCD, it has been shown that, on a large torus, the low energy constants in $\mathcal{L}_{\mathrm{eff}}$ are not affected by finite-size effects [24].

If $U(x) \in \mathrm{SU}(N_f)$ collects the Goldstone fields, the partition function is:

$$Z^\theta(N_f) = \int [dU] \exp\left[- \int_V d^4x \; \mathcal{L}_{\mathrm{eff}}^{(N_f)}(U, \partial U, M e^{i\theta/N_f}) \right]. \tag{2.22}$$

In this framework, the projection on a given winding number yields [21]:

$$\begin{aligned} Z_\nu(N_f) &= \int \frac{d\theta}{2\pi}\, e^{-i\nu\theta} \int [dU] \exp\left[- \int_V d^4x \; \mathcal{L}_{\mathrm{eff}}^{(N_f)}(U, M e^{i\theta/N_f}) \right] && (2.23) \\ &= \frac{1}{2\pi} \int [d\tilde{U}] (\det \tilde{U})^\nu \exp\left[- \int_V d^4x \; \mathcal{L}_{\mathrm{eff}}^{(N_f)}(\tilde{U}, M) \right], && (2.24) \end{aligned}$$

with $\tilde{U}(x) = U(x) \exp(-i\theta/N_f)$. The path integral over $\mathrm{SU}(N_f)$ for the partition function Z^θ ends up with an integral over $\mathrm{U}(N_f)$ for Z_ν. Because of the invariance properties of the measures $[dU]$ and $[d\tilde{U}]$, we have for any $V_1, V_2 \in \mathrm{U}(N_f)$:

$$Z_\nu(N_f|V_1 M V_2) = (\det V_1 V_2)^\nu Z_\nu(N_f|M). \tag{2.25}$$

The low-energy constants in $\mathcal{L}_{\mathrm{eff}}$ are volume-independent and N_f-dependent order parameters. In particular, a partial restoration of chiral symmetry would make some of them vanish. Since the relative size of these order parameters vary with N_f, the organization of the double expansion (2.21) depends on the phase in which the theory is considered.

1. If the number of light flavours N_f is fixed below $n_{\mathrm{crit}}(N_c)$, the quark condensate $\Sigma(N_f)$ is the order parameter that dominates the description of SBχS for sufficiently small quark masses (or sufficiently large volumes). The leading order of the effective Lagrangian involves only a kinetic term and a term linear in the quark mass matrix:

$$\mathcal{L}_2^{(N_f)} = \frac{1}{4} F^2(N_f) \langle \partial_\mu U^\dagger \partial_\mu U \rangle - \frac{1}{2} \Sigma(N_f) \langle U^\dagger M + M^\dagger U \rangle. \tag{2.26}$$

F is the decay constant of the Goldstone bosons and $\Sigma(N_f)$ is the quark condensate, introduced in Sec. I in Eqs. (1.3) and (1.2). The expansion of the effective Lagrangian is organized in this case through the standard power counting [22]: $\partial \sim p$, $M \sim p^2$, so that the next-to-leading order is $O(p^4)$.

2. On the other hand, for $N_f > n_{\mathrm{crit}}(N_c)$, the quark condensate vanishes and we cannot rely on the previous description anymore. In this case, the leading-order Lagrangian is the sum of the kinetic term, $\mathcal{L}_{(2,0)}$, and of a term quadratic in the quark masses, $\mathcal{L}_{(0,2)}$:

$$\mathcal{L}_{(2,0)}^{(N_f)} = \frac{F^2(N_f)}{4} \langle \partial_\mu U^\dagger \partial_\mu U \rangle, \tag{2.27}$$

$$\begin{aligned}\mathcal{L}_{(0,2)}^{(N_f)} = -\frac{1}{4} \big[&\mathcal{A}(N_f) \langle (U^\dagger M)^2 + (M^\dagger U)^2 \rangle + \mathcal{Z}_S(N_f) \langle U^\dagger M + M^\dagger U \rangle^2 \\ &+ \mathcal{Z}_P(N_f) \langle U^\dagger M - M^\dagger U \rangle^2 + \mathcal{H}(N_f) \langle M^\dagger M \rangle \big] .\end{aligned} \tag{2.28}$$

$\mathcal{L}_{(0,2)}$ appears in the standard $O(p^4)$ Lagrangian at the next-to-leading order, and the low-energy constants $\mathcal{Z}_S$, $\mathcal{Z}_P$, $\mathcal{A}$ and $\mathcal{H}$ correspond respectively to L_6, L_7, L_8 and H_2 of Ref. [22]. In this phase, the counting used to perform the expansion at higher orders is modified [23]: $\partial \sim M \sim p$.

In the generic case $N_f \geq 3$ (the case of two flavours is commented in App. B), $\mathcal{A}$, $\mathcal{Z}_S$ and $\mathcal{Z}_P$ are order parameters of SBχS. They are related to the low-energy behaviour of two-point correlators of the scalar and pseudoscalar densities[3] $S_a(x) = \bar{\psi}(x) t_a \psi(x)$ and $P_a(x) = \bar{\psi}(x) t_a i\gamma_5 \psi(x)$, where $\{t_a\}$ are flavour matrices. $\mathcal{A}$ stems from $\langle S_a S_b - P_a P_b \rangle$. $\mathcal{Z}_S$ is given by the correlator $\langle S_0 S_0 \delta_{ab} - S_a S_b \rangle$, and $\mathcal{Z}_P$ by $\langle P_0 P_0 \delta_{ab} - P_a P_b \rangle$: $\mathcal{Z}_S$ and $\mathcal{Z}_P$ violate the Zweig rule in the scalar and pseudoscalar channels respectively.

$\mathcal{H}$ is a high-energy counterterm, which is not an order parameter and cannot be measured in low-energy processes. Other similar counterterms arise at higher orders: they involve only the quark mass matrix M, but not the Goldstone boson fields U. These counterterms are needed to subtract short-distance singularities in QCD correlation functions of quark currents. Their general structure is dictated by the chiral symmetry, and it is reproduced by the high-energy counterterms on the level of the effective Lagrangian.

---

[3] Notice that contrary to the convention used in Refs. [23] and [35], the decay constant F^2 is not factorized in $\mathcal{L}_{(0,2)}$: $\mathcal{A}$, $\mathcal{Z}_S$ and $\mathcal{Z}_P$ carry the dimension (mass)^2.

3. For N_f just below the critical point $n_{\mathrm{crit}}(N_c)$, we expect a small (but non-vanishing) condensate and a large Zweig-rule violation in the scalar sector [9]. Linear and quadratic mass terms in the effective Lagrangian may be of comparable size. To take into account this possibility, we include both of them in the leading order of the Lagrangian:

$$\begin{aligned}\tilde{\mathcal{L}}_2^{(N_f)} = \frac{1}{4}\big[&F^2(N_f)\langle\partial_\mu U^\dagger \partial_\mu U\rangle - 2\Sigma(N_f)\langle U^\dagger M + M^\dagger U\rangle \\ &-\mathcal{A}(N_f)\langle (U^\dagger M)^2 + (M^\dagger U)^2\rangle - \mathcal{Z}_S(N_f)\langle U^\dagger M + M^\dagger U\rangle^2 \\ &-\mathcal{Z}_P(N_f)\langle U^\dagger M - M^\dagger U\rangle^2 - \mathcal{H}(N_f)\langle M^\dagger M\rangle\big]\,.\end{aligned} \tag{2.29}$$

This Lagrangian can be actually viewed as the lowest order of another systematic expansion scheme, defined by the generalized chiral counting [23]: $\partial \sim M \sim B \sim O(p)$. In this case, the next-to-leading order counts as $O(p^3)$.

The standard and generalized counting rules are only two different ways of expanding the same effective Lagrangian:

$$\mathcal{L}_{\mathrm{eff}} = \mathcal{L}_2 + \mathcal{L}_4 + \ldots = \tilde{\mathcal{L}}_2 + \tilde{\mathcal{L}}_3 + \ldots \tag{2.30}$$

At a given order in p, Generalized χPT includes terms relegated by Standard χPT to higher orders. At the lowest order, Eq. (2.29) can be applied even if the quark condensate dominates. On the other hand, the Standard χPT becomes inaccurate in the vicinity of the critical point where $\Sigma \sim 0$, whereas Generalized χPT may be more appropriate to describe the transition.

III. LEADING LARGE-VOLUME BEHAVIOUR OF THE INVERSE MOMENTS

A. Matching QCD and the effective theory

If we analyze perturbatively the partition function (2.22), the only difference from the case of an infinite volume lies in the meson propagator, because of the periodic boundary conditions:

$$G(x) = \frac{1}{V}\sum_p \frac{e^{ipx}}{M_\pi^2 + p^2}, \tag{3.1}$$

where $p_\mu = 2\pi n_\mu/L$, with n_μ integers. The contribution of the mode $p = 0$ in this propagator blows up when pions become massless [27]. Graphs containing such zero modes will diverge in the chiral limit, whereas the non-zero modes are suppressed in the large-volume limit: the fluctuations of the zero modes are not Gaussian and cannot be treated perturbatively. To cope with them, we split the Goldstone boson fields in two unitary matrices: $U(x) = U_0 U_1(x)$, where the constant factor U_0 describes the zero modes and $U_1(x)$ the remaining non-zero modes.

In a first approximation, the Gaussian fluctuations of U_1 can be neglected and the path integral in Z reduces to a group integral over constant SU(N_f) matrices:

$$Z(N_f) = \mathcal{D}\int_{\mathrm{SU}(N_f)} [dU_0] \exp\left[-V\mathcal{L}_{\mathrm{eff}}^{(N_f)}(U_0, M\exp(i\theta/N_f))\right]. \tag{3.2}$$

where $[dU_0]$ is the Haar measure over the group, and $\mathcal{D}$ a normalization constant, independent of the mass. The projection on a topological sector (2.24) becomes:

$$Z_\nu(N_f) = \frac{1}{2\pi}\mathcal{D}\int_{\mathrm{U}(N_f)} [d\tilde{U}_0](\det\tilde{U}_0)^\nu \exp\left[-V\mathcal{L}_{\mathrm{eff}}^{(N_f)}(\tilde{U}_0, M)\right]. \tag{3.3}$$

To simplify the notations, we replace $\tilde{U}_0$ by U in the calculations at the leading order of Z_ν. In addition, the N_f-dependence of the low-energy constants will not be explicitly denoted from now on, unless its presence is mandatory for understanding.

We want to expand Z_ν with respect to the size of the box and to the quark mass matrix. Actually, Eq. (3.2) tells us how to organize this from the expansion of $\mathcal{L}_{\mathrm{eff}}$. At the leading order, the partition function will depend on a simple scaling variable $X = ML^\kappa$. Below $n_{\mathrm{crit}}(N_c)$, we have $\kappa = 4$ (c.f. Eq. (2.26)), whereas the phase with a vanishing condensate yields $\kappa = 2$ (c.f. Eq. (2.29)). For small X, the expansion of Z_ν reads:

$$\begin{aligned} Z_\nu = \mathcal{N}_\nu(\det X)^\nu[1 &+ a_\nu\langle X^\dagger X\rangle \\ &+ b_\nu\langle X^\dagger X\rangle^2 + c_\nu\langle(X^\dagger X)^2\rangle + O(X^6)], \end{aligned} \tag{3.4}$$

where the coefficients $\mathcal{N}_\nu$, a_ν, b_ν, c_ν do not depend on M. This expansion is valid for $\nu \geq 0$: for a negative ν, $(\det X^\dagger)^{|\nu|}$ arises instead of $(\det X)^\nu$. The calculations are very similar in both cases, and our future results can be translated for any winding number by writing $|\nu|$ instead of ν.

The QCD partition function was expanded as a polynomial in the quark masses in Eq. (2.11), leading to:

$$\begin{aligned} Z_\nu = \mathcal{C}'_\nu L^{-\kappa\nu N_f}(\det{}_f X)^\nu & \\ \Bigg[1 + \frac{1}{L^{2\kappa}}\langle X^\dagger X\rangle\, \langle\!\langle\sigma_2\rangle\!\rangle_\nu^{(N_f)} &- \frac{1}{2L^{4\kappa}}\langle(X^\dagger X)^2\rangle\, \langle\!\langle\sigma_4\rangle\!\rangle_\nu^{(N_f)} \\ + \frac{1}{2L^{4\kappa}}\langle X^\dagger X\rangle^2\, \langle\!\langle(\sigma_2)^2\rangle\!\rangle_\nu^{(N_f)} &+ O(X^6)\Bigg]. \end{aligned} \tag{3.5}$$

By identifying the same powers of X in both expansions, we obtain relations between parameters of the effective Lagrangian and the leading large-volume behaviour of inverse moments.

When we compare Eqs. (3.4) and (3.5), we have to take into account the divergences of the inverse moments σ_k, as stressed in Eq. (2.18):

$$Z_\nu = \tilde{Z}_\nu \exp\left[D_2\langle M^\dagger M\rangle - \frac{1}{2}D_4\langle(M^\dagger M)^2\rangle\right] \sim Z_\nu^{\chi\mathrm{PT}}. \tag{3.6}$$

These counterterms, built from traces of the quark mass matrix, are also present in the χPT expression of the partition function. Therefore, the divergent behaviour of the inverse moments (e.g D_2 for σ_2) is tracked by counterterms in the χPT Lagrangian (in this case, $\mathcal{H}$). Divergence-free sum rules are found by considering linear combinations where the related χPT counterterms cancel.

B. $N_f \ll n_{\rm crit}(N_c)$: Leutwyler-Smilga sum rules

This case has already been treated with great details in Ref. [21]. We briefly review the main steps of the derivation of Leutwyler-Smilga sum rules for the reader's convenience. Eq. (3.3) yields at the leading order:

$$Z_\nu(N_f) = \frac{1}{2\pi}\mathcal{D}\int_{\mathrm{U}(N_f)}[dU](\det\ U)^\nu \exp\left[\frac{\Sigma V}{2}\langle U^\dagger M + M^\dagger U\rangle\right]. \tag{3.7}$$

$VM\Sigma$ is the only parameter of the group integral, and the scaling variable is $X = ML^4$ ($\kappa = 4$). In the general case of an arbitrary matrix M, a formula for the integral (3.7) is discussed in Ref. [28]. For our present purpose, it is however sufficient to follow the original method described in Ref. [21] to expand Eq. (3.7) in powers of M. We obtain the expansion coefficients a_ν, b_ν, …through two derivative operators, applied on both expressions of Z_ν: the group integral (3.7) and the X-expansion (3.4). The latter gives:

$$\begin{aligned}\sum_a \frac{\partial}{\partial X_a}\frac{\partial}{\partial X_a^*}Z_\nu = {}&\mathcal{N}_\nu(\det X)^\nu \\ &\times\left\{\frac{N_f K}{2}a_\nu + \langle X^\dagger X\rangle\left[(N_f K+1)b_\nu + (N_f+K)c_\nu\right] + O(X^4)\right\},\end{aligned} \tag{3.8}$$

and

$$\begin{aligned}\sum_{abcd}\langle t_a t_b t_c t_d\rangle \frac{\partial}{\partial X_a}\frac{\partial}{\partial X_b^*}\frac{\partial}{\partial X_c}\frac{\partial}{\partial X_d^*}Z_\nu = {}&\mathcal{N}_\nu(\det X)^\nu \\ &\times\frac{N_f K}{8}\left\{(N_f+K)b_\nu + (N_f K+1)c_\nu + O(X^2)\right\},\end{aligned} \tag{3.9}$$

where $K = N_f + \nu$, and X_a are the coordinates of X on $\{t_a\}$ ($a = 0 \ldots N_f^2 - 1$), which is a complete set of Hermitian matrices (see App. A).

The same derivative operators are applied on the group integral (3.7):

$$\sum_a \frac{\partial}{\partial X_a}\frac{\partial}{\partial X_a^*}Z_\nu = \frac{1}{8}N_f\Sigma^2 Z_\nu, \tag{3.10}$$

$$\sum_{abcd}\langle t_a t_b t_c t_d\rangle \frac{\partial}{\partial X_a}\frac{\partial}{\partial X_b^*}\frac{\partial}{\partial X_c}\frac{\partial}{\partial X_d^*}Z_\nu = \frac{1}{256}N_f\Sigma^4 Z_\nu. \tag{3.11}$$

Once Z_ν is replaced by its X-expansion (3.4) on the right hand-side of Eqs. (3.10) and (3.11), these equations yield polynomials in X, which are identified with Eqs. (3.8) and (3.9) order by order in powers of X. We get thus a_ν, and a linear system of two equations for b_ν and c_ν.

Once a_ν, b_ν and c_ν computed, the comparison of Eqs. (3.4) and (3.5) leads to the Leutwyler-Smilga sum rules:

$$\langle\langle\sigma_2\rangle\rangle_\nu^{(N_f)} = a_\nu = \frac{[V\Sigma(N_f)]^2}{4K}, \tag{3.12}$$

$$\langle\langle(\sigma_2)^2\rangle\rangle_\nu^{(N_f)} = 2b_\nu = \frac{[V\Sigma(N_f)]^4}{16(K^2-1)}, \tag{3.13}$$

$$\langle\langle\sigma_4\rangle\rangle_\nu^{(N_f)} = -2c\nu = \frac{[V\Sigma(N_f)]^4}{16K(K^2-1)}. \tag{3.14}$$

Because of $K = N_f + |\nu|$, the sum rules (3.12)-(3.14) depend explicitly on the number of flavours, but there is another (implicit and unknown) dependence stemming from the quark condensate $\Sigma(N_f)$. No divergent counterterm is explicitly present: these sum rules are derived from the leading order Lagrangian in Standard χPT, and they show only an asymptotic behaviour, valid for $V \to \infty$. For instance, σ_2 and $(\sigma_2)^2$ contain divergent subleading terms[4].

C. $N_f > n_{\mathrm{crit}}(N_c)$: the phase with a vanishing quark condensate

For $N_f > n_{\mathrm{crit}}(N_c)$, the integral defining Z_ν in terms of the effective Lagrangian (3.3) involves quadratic mass terms at the leading order:

$$\begin{aligned} Z_\nu(N_f) = \frac{1}{2\pi}\mathcal{D}\int_{\mathrm{U}(N_f)} [dU](\det U)^\nu & \qquad (3.15)\\ \times \exp\Bigg[\frac{V}{4}\Big\{\mathcal{A}\langle (U^\dagger M)^2 + (M^\dagger U)^2\rangle + \mathcal{Z}_S\langle U^\dagger M + M^\dagger U\rangle^2 & \\ + \mathcal{Z}_P\langle U^\dagger M - M^\dagger U\rangle^2 + \mathcal{H}\langle M^\dagger M\rangle\Big\}\Bigg]. & \end{aligned}$$

The scaling variable is now $X = ML^2$ ($\kappa = 2$). The counterterm $\mathcal{H}$ has the same structure as the divergent term D_2 due to σ_2 in Eq. (3.6). To eliminate this divergence, it is natural to introduce the ν-dependent fluctuation $\bar\sigma_2 = \sigma_2 - \langle\!\langle \sigma_2 \rangle\!\rangle_\nu^{(N_f)}$. The subtraction of this quadratic divergence leads to the loss of a single sum rule, for instance $\langle\!\langle \sigma_2 \rangle\!\rangle_0^{(N_f)}$. For the other topological sectors, we can indeed write sum rules concerning $\langle\!\langle \sigma_2 \rangle\!\rangle_\nu^{(N_f)} - \langle\!\langle \sigma_2 \rangle\!\rangle_0^{(N_f)}$, since the (short-distance) divergence due to $\mathcal{H}$ is insensitive to the (topological) winding number.

Because of chirality, the integral (3.15) vanishes unless the same power of U and $U^\dagger$ arises. The determinant $(\det U)^\nu$ counts as the νN_f-th power of U, whereas the exponential involves only the square of $U^\dagger$. Therefore, the phase of an odd $N_f > n_{\mathrm{crit}}(N_c)$ discriminates between the topological sectors: the odd-ν sectors are suppressed in the large-volume limit compared to the even winding numbers (this discrimination does not occur for an even number of flavours). As a matter of fact, the symmetry $M \to -M$ is equivalent to $\theta \to \theta + \pi N_f$. From the Fourier decomposition (2.6), we can directly check that the odd topological sectors have a vanishing partition function at the leading order, provided that N_f is odd. Of course, higher orders of the effective Lagrangian (for instance $\tilde{\mathcal{L}}_3$) contribute to the odd topological sectors, giving finally rise for Z_ν to a different volume dependence from the even winding numbers.

In the topologically trivial sector $\nu = 0$, $(\det U)^\nu$ disappears from the group integral and the exponential in (3.15) can be directly expanded in powers of X and integrated over U(N).

---

[4] For this reason, the formulae (3.12) and (3.13) should be applied to finite volumes with great care.

Using App. A, the computation of the lowest powers in the X-expansion is straightforward, leading to the sum rules:

$$\langle\!\langle (\bar{\sigma}_2)^2 \rangle\!\rangle_0 = \frac{V^2}{16N_f^2(N_f^2-1)} \tag{3.16}$$
$$\times[4(2N_f^2+1)(\mathcal{Z}_S^2+\mathcal{Z}_P^2) - 8\mathcal{Z}_S\mathcal{Z}_P - 8N_f\mathcal{A}(\mathcal{Z}_S+\mathcal{Z}_P) + 4N_f^2\mathcal{A}^2],$$

$$\langle\!\langle \sigma_4 \rangle\!\rangle_0 = \frac{V^2}{16N_f(N_f^2-1)} \tag{3.17}$$
$$\times[12(\mathcal{Z}_S^2+\mathcal{Z}_P^2) - 8\mathcal{Z}_S\mathcal{Z}_P - 8N_f\mathcal{A}(\mathcal{Z}_S+\mathcal{Z}_P) + 4\mathcal{A}^2].$$

As emphasized in the previous section, these sum rules depend on the number of massless flavours in an explicit way, but also implicitly through the N_f-dependent order parameters $\mathcal{A}$, $\mathcal{Z}_S$ and $\mathcal{Z}_P$.

These sum rules predict a different large-volume behaviour from the Leutwyler-Smilga sum rules (3.12)-(3.14). This agrees with our general expectation concerning the large-volume dependence of the (suitably averaged) small Dirac eigenvalues [13]. The eigenvalues accumulating like $1/L^4$ contribute to SBχS and to the quark condensate. Correspondingly, for $N_f < n_{\rm crit}(N_c)$, the asymptotic behaviour of the sum rules is:

$$\left\langle\!\!\left\langle \sum_n{}' \frac{1}{\lambda_n^2} \right\rangle\!\!\right\rangle_0 \sim V^2, \qquad \left\langle\!\!\left\langle \sum_n{}' \frac{1}{\lambda_n^4} \right\rangle\!\!\right\rangle_0 \sim V^4. \tag{3.18}$$

On the other hand, the $1/L^2$-eigenvalues do not contribute to the quark condensate, but may still contribute to SBχS in the phase above $n_{\rm crit}(N_c)$, through a non-vanishing value of $F^2(N_f)$. Indeed, Eqs. (3.16) and (3.17) predict in this phase an infinite-volume limit of V^2 for $\langle\!\langle (\bar{\sigma}_2)^2 \rangle\!\rangle_0$ and $\langle\!\langle \sigma_4 \rangle\!\rangle_0$, as expected.

IV. THE APPROACH TO THE CRITICAL POINT

A. Leading large-volume behaviour

We want now to study the intermediate case, where the linear and the quadratic mass terms in the effective Lagrangian may compete for some range of volumes. To understand which results can be expected, it is instructive to consider first χPT in an infinite volume and to imagine that we let the quark masses vary. If the quark condensate is (even slightly) different from zero, we can always find sufficiently small quark masses for which the linear mass term is dominant. When the quarks become massive, the corrections due to the quadratic mass terms may become discernible and even preponderant, provided that the quark condensate is not too large to hide their effects.

In this paper, we work in a box with a fixed large volume, and M_π^2 is counted as $O(1/L^4)$. The variation of the quark masses is therefore translated into a change of the volume. For $N_f < n_{\rm crit}(N_c)$, the Leutwyler-Smilga sum rules derived in SχPT should correctly describe the volume-dependence of the inverse moments when L tends to infinity. However, close to the critical point and for a given value of the volume, the quark condensate need not be large enough to make $\mathcal{L}_2$, Eq. (2.26), dominate. This could lead to significant deviations from the asymptotic limit even for large volumes.

Hence, the leading order of the Lagrangian is $\tilde{\mathcal{L}}_2$, Eq. (2.29), and Z_ν reads:

$$\begin{aligned} Z_\nu = \frac{1}{2\pi}\mathcal{D}\int_{\mathrm{U}(N_f)} [dU](\det U)^\nu \\ \times \exp\Bigg[\frac{V}{4}\Big\{2\Sigma\langle U^\dagger M + M^\dagger U\rangle + \mathcal{A}\langle (U^\dagger M)^2 + (M^\dagger U)^2\rangle \\ +\mathcal{Z}_S\langle U^\dagger M + M^\dagger U\rangle^2 + \mathcal{Z}_P\langle U^\dagger M - M^\dagger U\rangle^2 + \mathcal{H}\langle M^\dagger M\rangle\Big\}\Bigg]. \end{aligned} \tag{4.1}$$

$X = ML^2$ remains the scaling parameter for the mass, and ΣL^2 is the expansion variable for the quark condensate. This organizes the expansion through the power counting $\Sigma \sim M \sim 1/L^2$, similar to GχPT. We shall therefore consider the theory for volumes and masses so that X and ΣL^2 are of order 1.

In order to evaluate (4.1), it is convenient to define the group integral I_ν for arbitrary complex numbers $(b, \bar{b}, z, \bar{z}, y, a, \bar{a})$:

$$\begin{aligned} I_\nu = \int_{\mathrm{U}(N_f)} [dU]\ (\det U)^\nu \\ \times \exp[b\langle XU^\dagger\rangle + \bar{b}\langle X^\dagger U\rangle + z\langle XU^\dagger\rangle^2 + \bar{z}\langle X^\dagger U\rangle^2 \\ +y\langle XU^\dagger\rangle\langle X^\dagger U\rangle + a\langle (XU^\dagger)^2\rangle + \bar{a}\langle (X^\dagger U)^2\rangle], \end{aligned} \tag{4.2}$$

The partition function at a fixed winding number reads:

$$Z_\nu = \frac{1}{2\pi}\mathcal{D}\exp[h^0\langle X^\dagger X\rangle] I_\nu(b^0, \bar{b}^0, z^0, \bar{z}^0, y^0, a^0, \bar{a}^0; X), \tag{4.3}$$

where I_ν is calculated with the values:

$$b^0 = \bar{b}^0 = \frac{1}{2}L^2\Sigma, \tag{4.4}$$

$$z^0 = \bar{z}^0 = \frac{1}{4}(\mathcal{Z}_S + \mathcal{Z}_P), \qquad y^0 = \frac{1}{2}(\mathcal{Z}_S - \mathcal{Z}_P), \tag{4.5}$$

$$a^0 = \bar{a}^0 = \frac{1}{4}\mathcal{A}, \qquad h^0 = \frac{1}{4}\mathcal{H}. \tag{4.6}$$

I_ν is a polynomial in $(b, \bar{b}, z, \bar{z}, y, a, \bar{a})$, and its derivatives are not independent:

$$\frac{\partial^2 I_\nu}{\partial b^2} = \frac{\partial I_\nu}{\partial z} \qquad \frac{\partial^2 I_\nu}{\partial \bar{b}^2} = \frac{\partial I_\nu}{\partial \bar{z}} \qquad \frac{\partial^2 I_\nu}{\partial b \partial \bar{b}} = \frac{\partial I_\nu}{\partial y} \tag{4.7}$$

We expand this integral in powers of X, with coefficients that are independent of the quark mass matrix:

$$\begin{aligned} I_\nu = (\det X)^\nu[\alpha_\nu + \beta_\nu\langle X^\dagger X\rangle + \gamma_\nu\langle X^\dagger X\rangle^2 + \delta_\nu\langle (X^\dagger X)^2\rangle \\ +\epsilon_\nu\langle X^\dagger X\rangle^3 + \eta_\nu\langle (X^\dagger X)^2\rangle\langle X^\dagger X\rangle + \kappa_\nu\langle (X^\dagger X)^3\rangle + O(X^8)], \end{aligned} \tag{4.8}$$

We identify the same powers of X in the expression of Z_ν in terms of averaged inverse moments (3.5) and in its expression at the leading order of the effective Lagrangian, obtained from Eqs. (4.3) and (4.8). This leads to the sum rules:

$$\langle\langle \sigma_2 \rangle\rangle_\nu^{(N_f)} = V\left(\frac{\beta_\nu}{\alpha_\nu} + h\right) \tag{4.9}$$

$$\langle\langle (\sigma_2)^2 \rangle\rangle_\nu^{(N_f)} = 2V^2\left(\frac{\gamma_\nu}{\alpha_\nu} + h\frac{\beta_\nu}{\alpha_\nu} + \frac{h^2}{2}\right) \tag{4.10}$$

$$\langle\langle \sigma_4 \rangle\rangle_\nu^{(N_f)} = -2V^2\frac{\delta_\nu}{\alpha_\nu} \tag{4.11}$$

$$\langle\langle (\bar\sigma_2)^2 \rangle\rangle_\nu^{(N_f)} = V^2\left(2\frac{\gamma_\nu}{\alpha_\nu} - \left(\frac{\beta_\nu}{\alpha_\nu}\right)^2\right) \tag{4.12}$$

$$\langle\langle (\bar\sigma_2)^3 \rangle\rangle_\nu^{(N_f)} = V^3\left(6\frac{\epsilon_\nu}{\alpha_\nu} - 6\frac{\beta_\nu}{\alpha_\nu}\frac{\gamma_\nu}{\alpha_\nu} + 2\left(\frac{\beta_\nu}{\alpha_\nu}\right)^3\right) \tag{4.13}$$

$$\langle\langle \bar\sigma_2\sigma_4 \rangle\rangle_\nu^{(N_f)} = V^3\left(-2\frac{\eta_\nu}{\alpha_\nu} + 2\frac{\beta_\nu}{\alpha_\nu}\frac{\delta_\nu}{\alpha_\nu}\right) \tag{4.14}$$

$$\langle\langle \sigma_6 \rangle\rangle_\nu^{(N_f)} = 3V^3\kappa_\nu \tag{4.15}$$

If we know α_ν, β_ν,... in terms of the low-energy constants of $\tilde{\mathcal{L}}_2$, Eqs. (4.9)-(4.15) lead to the desired sum rules. The high-energy counterterm h, which reflects the ultraviolet divergence in σ_2, has to be eliminated. This can be obtained if we consider the fluctuation of σ_2 over a topological sector: $\bar\sigma_2 = \sigma_2 - \langle\langle\sigma_2\rangle\rangle_\nu^{(N_f)}$, as defined in Sec. III C.

For the topologically trivial sector $\nu = 0$, the computation is very simple, following the same line as for the phase $N_f > n_{\mathrm{crit}}(N_c)$. This leads to the expansion coefficients (for $b = \bar b$, $z = \bar z$, $a = \bar a$):

$$\alpha_0 = 1 \qquad \beta_0 = \frac{1}{N_f}(y + b^2) \tag{4.16}$$

$$\begin{aligned}\gamma_0 = &\frac{1}{N_f(N_f^2-1)}\\ &\times\left\{N_f[\frac{b^4}{2} + 2b^2y + 2b^2z + y^2 + 2z^2 + 2a^2] - 2a[b^2+2z]\right\}\end{aligned} \tag{4.17}$$

$$\begin{aligned}\delta_0 = &\frac{1}{N_f(N_f^2-1)}\\ &\times\left\{-[\frac{b^4}{2} + 2b^2z + 2b^2y + y^2 + 2z^2 + 2a^2] + N_f\cdot 2a[b^2+2z]\right\}\end{aligned} \tag{4.18}$$

$$\begin{aligned}\epsilon_0 = &\frac{1}{N_f(N_f^2-1)(N_f^2-4)}\\ &\times\left\{6(N_f^2-2)\left[\frac{b^6}{36} + b^4\left(\frac{z}{3}+\frac{y}{4}\right) + b^2\left(z^2 + \frac{y^2}{2} + yz\right) + \left(\frac{y^3}{6} + yz^2\right)\right]\right.\\ &\qquad\left. + 2(N_f^2+2)\left[b^2+y\right]a^2 - 12N_f\left[\frac{b^4}{6} + b^2\left(\frac{y}{2}+z\right) + yz\right]a\right\}\end{aligned} \tag{4.19}$$

$$\eta_0 = \frac{1}{N_f(N_f^2-1)(N_f^2-4)} \tag{4.20}$$

$$\times\left\{-18N_f\left[\frac{b^6}{36}+b^4\left(\frac{z}{3}+\frac{y}{4}\right)+b^2\left(z^2+\frac{y^2}{2}+yz\right)+\left(\frac{y^3}{6}+yz^2\right)\right]\right.$$

$$\left.-18N_f\left[b^2+y\right]a^2+12(N_f^2+2)\left[\frac{b^4}{6}+b^2\left(\frac{y}{2}+z\right)+yz\right]a\right\}$$

$$\kappa_0 = \frac{1}{N_f(N_f^2-1)(N_f^2-4)} \tag{4.21}$$

$$\left\{24\left[\frac{b^6}{36}+b^4\left(\frac{z}{3}+\frac{y}{4}\right)+b^2\left(z^2+\frac{y^2}{2}+yz\right)+\left(\frac{y^3}{6}+yz^2\right)\right]\right.$$

$$\left.+4(N_f^2+2)\left[b^2+y\right]a^2-24N_f\left[\frac{b^4}{6}+b^2\left(\frac{y}{2}+z\right)+yz\right]a\right\} \tag{4.22}$$

Before focusing on the resulting sum rules for the topologically trivial sector $\nu = 0$, we sketch the general derivation of the expansion coefficients for an arbitrary winding number.

B. Topologically non-trivial sectors: $\nu \neq 0$

Let us begin with the leading coefficient α_ν. Independent of X, it can be computed for $X = x \cdot 1$, where x is a complex number. α_ν is then given by the leading order of I_ν in x (without any power of x^*), and it depends only on (b, z, a). As a matter of fact, $\alpha_\nu(b, z, a)$ can be deduced from $\alpha_\nu(b, 0, a)$ because of the relations between the derivatives (4.7). The problem reduces to obtaining the leading order in x of the group integral:

$$I_\nu^\alpha = I_\nu(b, a; x\cdot 1) = \int_{\mathrm{U}(N_f)} [dU](\det U)^\nu \exp[bx\langle U^\dagger\rangle + ax^2\langle {U^\dagger}^2\rangle]. \tag{4.23}$$

The Appendix C 1 describes how $\alpha_\nu(b, 0, a)$ is extracted from this integral, leading to the polynomial:

$$\alpha_\nu(b, z=0, a) = \sum_{m=0\ldots\nu N_f/2} b^{\nu N_f-2m} a^m c_m, \tag{4.24}$$

where $\{c_m\}$ are purely combinatorial coefficients. Using $\partial^2\alpha_\nu/\partial b^2 = \partial\alpha_\nu/\partial z$, we obtain the general expression of α_ν:

$$\alpha_\nu(b, z, a) = \sum_{l+2m+2p=\nu N_f} b^l a^m z^p \frac{(l+2p)!}{l!p!} c_m. \tag{4.25}$$

In the limit case of a vanishing quark condensate ($b = 0$), we check that α_ν (and therefore I_ν) vanishes if νN_f is odd, in agreement with the parity discrimination discussed in Sec. III C.

We obtain the next coefficients by applying the derivative operators of Eqs. (3.8) and (3.9) on both representations of I_ν: the group integral (4.2) and the X-expansion (4.8). We already know the result of the latter from the phase $N_f \ll n_{\mathrm{crit}}(N_c)$, studied in Sec III B:

$$
\begin{aligned}
&\sum_a \frac{\partial}{\partial X_a}\frac{\partial}{\partial X_a^*} I_\nu \qquad (4.26)\\
&\quad = (\det X)^\nu \left\{ \frac{N_f K}{2}\beta_\nu + \langle X^\dagger X\rangle \left[(N_f K+1)\gamma_\nu + (N_f+K)\delta_\nu\right] + O(X^4) \right\},
\end{aligned}
$$

$$
\begin{aligned}
&\sum_{abcd} \langle t_a t_b t_c t_d\rangle \frac{\partial}{\partial X_a}\frac{\partial}{\partial X_b^*}\frac{\partial}{\partial X_c}\frac{\partial}{\partial X_d^*} I_\nu \qquad (4.27)\\
&\quad = (\det X)^\nu \frac{N_f K}{8}\left\{ (N_f+K)\gamma_\nu + (N_f K+1)\delta_\nu + O(X^2)\right\}.
\end{aligned}
$$

The two-derivative operator, applied on the group integral (4.2) that defines I_ν, leads to:

$$
\begin{aligned}
\sum_a \frac{\partial}{\partial X_a}\frac{\partial}{\partial X_a^*} I_\nu = \Bigg[&\frac{N_f}{2}(y+b\bar{b}) + 2a\bar{a}\langle X^\dagger X\rangle \\
&+(N_f z\bar{b} + a\bar{b} + \frac{N_f}{2}by)\frac{\partial}{\partial b} + (N_f \bar{z} b + \bar{a} b + \frac{N_f}{2}\bar{b}y)\frac{\partial}{\partial \bar{b}} \\
&+(N_f z + a)y\frac{\partial}{\partial z} + (N_f\bar{z} + \bar{a})y\frac{\partial}{\partial \bar{z}} \\
&+(2N_f z\bar{z} + \frac{N_f}{2}y^2 + 2\bar{a}z + 2a\bar{z})\frac{\partial}{\partial y}\Bigg] I_\nu. \qquad (4.28)
\end{aligned}
$$

We can now replace I_ν by its X-expansion (4.8), and identify the resulting polynomial in X with the right hand-side of Eq. (4.26). When we identify the coefficients of X^0, we obtain β_ν in terms of α_ν and its derivatives:

$$
\alpha_\nu' = \frac{\partial \alpha_\nu}{\partial b}, \qquad \dot{\alpha}_\nu = \frac{\partial \alpha_\nu}{\partial a}, \qquad \alpha_\nu'' = \frac{\partial^2 \alpha_\nu}{\partial b^2} = \frac{\partial \alpha_\nu}{\partial z}. \qquad (4.29)
$$

The coefficients of $\langle X^\dagger X\rangle$ lead to an equality between a linear combination of γ_ν and δ_ν, and some derivatives of α_ν and β_ν (these derivatives can actually be rewritten only in terms of derivatives of α_ν, since we know how β_ν is related to α_ν).

We follow the same line with the four-derivative operator. Actually, when we apply the operator to the group integral (4.2), we only need the lowest power of X, to compare it with (4.27). Factors of higher degrees, similar to $a\bar{a}\langle X^\dagger X\rangle$ in Eq. (4.28) can be ignored, and we obtain:

$$
\begin{aligned}
&\sum_{abcd} \langle t_a t_b t_c t_d\rangle \frac{\partial}{\partial X_a}\frac{\partial}{\partial X_b^*}\frac{\partial}{\partial X_c}\frac{\partial}{\partial X_d^*} I_\nu \qquad (4.30)\\
&\quad = \Bigg\{ \frac{N_f}{8}\Bigg[\frac{1}{2}b^2\bar{b}^2 + b^2(N_f\bar{a} + \bar{z}) + \bar{b}^2(N_f a + z) + 2b\bar{b}y \\
&\qquad\qquad +y^2 + 2z\bar{z} + 2a\bar{a} + 2N_f(a\bar{z} + \bar{a}z)\Bigg] \\
&\qquad +\frac{1}{8}\Big[b\bar{b}(N_f by + 2N_f\bar{b}z + 2\bar{b}a) + \bar{b}(6N_f yz + 4ay + 2N_f^2 ay) \\
&\qquad\qquad +b(2N_f y^2 + 4N_f^2\bar{a}z + 4N_f z\bar{z} + 4N_f a\bar{a} + 4a\bar{z})\Big]\frac{\partial}{\partial b}
\end{aligned}
$$

$$
\begin{aligned}
&+\frac{1}{8}\left[\frac{1}{2}b^2y^2+\bar{b}^2(2N_fz^2+4az)+b\bar{b}(4N_fyz+4ay)\right.\\
&\qquad +y^2(5N_fz+(N_f^2+4)a)+4N_f^2\bar{a}z^2\\
&\qquad \left.+8N_fa\bar{a}z+4N_fz^2\bar{z}+4a^2\bar{a}\right]\frac{\partial^2}{\partial b^2}\\
&+\frac{1}{4}\left[2N_f\bar{b}yz^2+N_fby^2z+aby^2+4a\bar{b}yz\right]\frac{\partial^3}{\partial b^3}+\frac{1}{4}[N_fz+2a]zy^2\frac{\partial^4}{\partial b^4}\\
&\left.+\frac{1}{4}[\bar{b}^2+2\bar{z}]a^2\frac{\partial}{\partial a}+\frac{1}{2}a^2\bar{b}y\frac{\partial^2}{\partial a\partial b}+\frac{1}{4}a^2y^2\frac{\partial^3}{\partial a\partial b^2}+O(X^2)\right\}I_\nu.
\end{aligned}
$$

We replace I_ν by its X-expansion on the right-hand side of this equation. We keep only the coefficient for X^0 and we compare it with Eq. (4.27), to end up with a second equality relating a linear combination of γ_ν and δ_ν to the derivatives of α_ν. The resulting expressions are listed in App. C 2, but it seems difficult to handle them in general.

C. Topologically trivial sector: $\nu = 0$

From the expansion coefficients α_0, β_0... of Sec. IV A, we get the sum rules for the inverse moments of degree 4 and 6. If we denote $\zeta = V\Sigma^2/\mathcal{A}$, $\bar{S} = \mathcal{Z}_S/\mathcal{A}$ and $\bar{P} = \mathcal{Z}_P/\mathcal{A}$, the sum rules read:

$$
\begin{aligned}
\langle\!\langle(\bar{\sigma}_2)^2\rangle\!\rangle_0^{(N_f)} = {} & \frac{V^2\mathcal{A}^2}{16N_f^2(N_f^2-1)}\\
&\times\{\zeta^2+\zeta[4(2N_f^2+1)\bar{S}-4\bar{P}-4N_f]\\
&\quad+[4(2N_f^2+1)(\bar{S}^2+\bar{P}^2)-8\bar{S}\bar{P}-8N_f(\bar{S}+\bar{P})+4N_f^2]\}
\end{aligned}
\tag{4.31}
$$

$$
\begin{aligned}
\langle\!\langle\sigma_4\rangle\!\rangle_0^{(N_f)} = {} & \frac{V^2\mathcal{A}^2}{16N_f(N_f^2-1)}\\
&\times\{\zeta^2+\zeta[12\bar{S}-4\bar{P}-4N_f]\\
&\quad+[12\bar{S}^2+12\bar{P}^2-8\bar{S}\bar{P}+4-8N_f\bar{S}-8N_f\bar{P}]\}
\end{aligned}
\tag{4.32}
$$

$$
\begin{aligned}
\langle\!\langle\sigma_6\rangle\!\rangle_0^{(N_f)} = {} & \frac{V^3\mathcal{A}^3}{32N_f(N_f^2-1)(N_f^2-4)}\\
&\times\left\{\zeta^3+\zeta^2[30\bar{S}-6\bar{P}-6N_f]\right.\\
&\quad+\zeta[180\bar{S}^2+36\bar{P}^2-72\bar{S}\bar{P}-72N_f\bar{S}+6(N_f^2+2)]\\
&\quad+[120\bar{S}^3-120\bar{P}^3+72\bar{S}\bar{P}^2-72\bar{S}^2\bar{P}-72N_f\bar{S}^2\\
&\qquad\left.+72N_f\bar{P}^2+12(N_f^2+2)\bar{S}-12(N_f^2+2)\bar{P}]\right\}
\end{aligned}
\tag{4.33}
$$

$$
\begin{aligned}
\langle\!\langle\sigma_4\bar{\sigma}_2\rangle\!\rangle_0^{(N_f)} = {} & \frac{V^3\mathcal{A}^3}{16N_f^2(N_f^2-1)(N_f^2-4)}\\
&\times\left\{\zeta^3+\zeta^2[2(2N_f^2+7)\bar{S}-6\bar{P}-6N_f]\right.\\
&\quad+\zeta[36(N_f^2+1)\bar{S}^2+4(N_f^2+5)\bar{P}^2-8(N_f^2+5)\bar{S}\bar{P}\\
&\qquad-8N_f(N_f^2+5)\bar{S}+4(2N_f^2+1)]\\
&\quad+[24(N_f^2+1)\bar{S}^3-24(N_f^2+1)\bar{P}^3+8(N_f^2+5)\bar{S}\bar{P}^2
\end{aligned}
\tag{4.34}
$$

$$
\begin{aligned}
&-8(N_f^2+5)\bar{S}^2\bar{P} - 8N_f(N_f^2+5)\bar{S}^2 + 8N_f(N_f^2+5)\bar{P}^2\\
&+8(2N_f^2+1)\bar{S} - 8(2N_f^2+1)\bar{P}]\big\}
\end{aligned}
$$

$$
\begin{aligned}
\langle\!\langle(\bar{\sigma}_2)^3\rangle\!\rangle_0^{(N_f)} = {} & \frac{V^3\mathcal{A}^3}{8N_f^3(N_f^2-1)(N_f^2-4)}\\
&\times\big\{\zeta^3+\zeta^2[6(N_f^2+1)\bar{S}-6\bar{P}-6N_f]\\
&\quad +\zeta[6(2N_f^4-N_f^2+2)\bar{S}^2+6(N_f^2+2)\bar{P}^2\\
&\qquad -12(N_f^2+2)\bar{S}\bar{P}-12N_f(N_f^2+2)\bar{S}+9N_f^2]\\
&\quad +[4(2N_f^4-N_f^2+2)\bar{S}^3-4(2N_f^4-N_f^2+2)\bar{P}^3\\
&\qquad +12(N_f^2+2)\bar{S}\bar{P}^2-12(N_f^2+2)\bar{S}^2\bar{P}\\
&\qquad -12N_f(N_f^2+2)\bar{S}^2+12N_f(N_f^2+2)\bar{P}^2\\
&\qquad +18N_f^2\bar{S}-18N_f^2\bar{P}]\big\}
\end{aligned}
\tag{4.35}
$$

The dependence on the number of massless flavours is not limited to the polynomials in N_f explicitly present in the previous formulae, since Σ, $\mathcal{Z}_S$, $\mathcal{Z}_P$ and $\mathcal{A}$ are unknown functions of N_f (this dependence is here omitted for typographical convenience). The singularities for $N_f=1$ (for $1/\lambda^4$- and $1/\lambda^6$-moments) and $N_f=2$ (for $1/\lambda^6$-moments) arise because some of the coefficients α_ν, $\beta_\nu\ldots$ in (4.8) are not independent in these cases, and we can only write (singularity-free) sum rules for differences between inverse moments of the same degree, e.g. $(\bar{\sigma}_2)^2-\sigma_4$ for $N_f=1$.

Notice that the scaling volume parameter $\zeta=V\Sigma^2/\mathcal{A}$ and the ratios $\bar{S}=\mathcal{Z}_S/\mathcal{A}$ and $\bar{P}=\mathcal{Z}_P/\mathcal{A}$ are invariant under the QCD renormalization group. This invariance occurs also for ratios of inverse moments with the same degree of homogeneity in λ:

$$
R=\frac{\langle\!\langle\sigma_4\rangle\!\rangle_0}{\langle\!\langle(\bar{\sigma}_2)^2\rangle\!\rangle_0},\quad S=\frac{\langle\!\langle(\bar{\sigma}_2)^3\rangle\!\rangle_0}{\langle\!\langle\sigma_6\rangle\!\rangle_0},\quad T=\frac{\langle\!\langle\sigma_4\bar{\sigma}_2\rangle\!\rangle_0}{\langle\!\langle\sigma_6\rangle\!\rangle_0},\quad U=\frac{\langle\!\langle\sigma_4\rangle\!\rangle_0^{3/2}}{\langle\!\langle\sigma_6\rangle\!\rangle_0}. \tag{4.36}
$$

We can plot (Figs. 1 and 2) the variation of R as a function of the volume, measured in physical units F_π^{-4} (F_π=92.4 MeV). The scaling parameter is $\zeta=(F_\pi^4V)/(16\hat{L}_8)$, where the dimensionless parameter $\hat{L}_8$ denotes $(F_\pi^4\mathcal{A})/(16\Sigma^2)$ (for $N_f=3$, it essentially corresponds to the SχPT low-energy constant L_8 of Ref. [22])[5]. A variation of the condensate means a variation of $\hat{L}_8$, and consequently a redefinition of the units used to measure the volume: this reduces to a simple shift of the curve (to the right if Σ decreases, to the left if it increases).

The infinite-volume limit reproduces the Leutwyler-Smilga sum rules ($R\to N_f$). On the other hand, since the scaling volume parameter is $\zeta=V\Sigma^2/\mathcal{A}$, the limit $L\to 0$ corresponds mathematically to a vanishing condensate for the sum rules: we recover the results of Sec. III C. The sum rules (4.31)-(4.35) interpolate between these regimes.

The ratios R, S, T and U are not very sensitive to $\bar{P}$ (Zweig-rule violation in the pseudoscalar channel) until we reach small volumes where large corrections stemming from higher orders are expected. In the case of $N_f = 3$ flavours, the value $\bar{P} = -1/2$ is privileged, because it guarantees the validity of the Gell-Mann–Okubo formula, independently of the size of Σ. On the other hand, it may be interesting to notice that some ratios are affected by variations of $\bar{S}$ even at intermediate volumes. For instance, the dependence of the ratio S on $\bar{S}$ is plotted on Fig. 3 (we choose $\hat{L}_8 = 0.1$, but other values of $\hat{L}_8$ can be obtained by a simple shift of the curve).

---

[5] In SχPT, the constant L_8 depends on the renormalization scale μ. At $\mu=M_\rho$, it is estimated as $L_8^r(M_\rho)=(0.9\pm0.3)\cdot10^{-3}$ (see for instance Ref. [29]). Close to the phase transition, L_8 should increase and become scale independent.

To simplify the analysis, it may be interesting to focus on linear combinations of the inverse moments in which the leading power of V cancels. These combinations therefore vanish in the limiting case of the Leutwyler-Smilga sum rules (3.12)-(3.14):

$$N_f \left\langle\!\left\langle (\bar{\sigma}_2)^2 \right\rangle\!\right\rangle_0^{(N_f)} - \langle\!\langle \sigma_4 \rangle\!\rangle_0^{(N_f)} = \frac{V^2}{4N_f}\{2\mathcal{Z}_S\Sigma^2 V + [2\mathcal{Z}_S^2 + 2\mathcal{Z}_P^2 + \mathcal{A}]\} \tag{4.37}$$

$$\begin{aligned} N_f \langle\!\langle \sigma_4\bar{\sigma}_2 \rangle\!\rangle_0^{(N_f)} - 2\,\langle\!\langle \sigma_6 \rangle\!\rangle_0^{(N_f)} &= \frac{V^3}{8N_f(N_f^2-1)} \\ \times\{2\mathcal{Z}_S\Sigma^4 V^2 + [18\mathcal{Z}_S^2 &+ 2\mathcal{Z}_P^2 - 4\mathcal{Z}_S\mathcal{Z}_P - 4N_f\mathcal{Z}_S\mathcal{A} + \mathcal{A}^2]\Sigma^2 V \\ &+[12(\mathcal{Z}_S^3 - \mathcal{Z}_P^3) + 4\mathcal{Z}_S\mathcal{Z}_P(\mathcal{Z}_S - \mathcal{Z}_P) \\ &\qquad -4N_f(\mathcal{Z}_S^2 - \mathcal{Z}_P^2)\mathcal{A} + 2(\mathcal{Z}_S - \mathcal{Z}_P)\mathcal{A}^2]\} \end{aligned} \tag{4.38}$$

$$\begin{aligned} N_f \left\langle\!\left\langle (\bar{\sigma}_2)^3 \right\rangle\!\right\rangle_0^{(N_f)} - 2\,\langle\!\langle \sigma_4\bar{\sigma}_2 \rangle\!\rangle_0^{(N_f)} &= \frac{V^3}{8N_f^2(N_f^2-1)} \\ \times\{2\mathcal{Z}_S\Sigma^4 V^2 + [6(2N_f^2+1)\mathcal{Z}_S^2 &+ 2\mathcal{Z}_P^2 - 4\mathcal{Z}_S\mathcal{Z}_P - 4N_f\mathcal{Z}_S\mathcal{A} + \mathcal{A}^2]\Sigma^2 V \\ &+[4(2N_f^2+1)(\mathcal{Z}_S^3 - \mathcal{Z}_P^3) + 4\mathcal{Z}_S\mathcal{Z}_P(\mathcal{Z}_S - \mathcal{Z}_P) \\ &\qquad -4N_f(\mathcal{Z}_S^2 - \mathcal{Z}_P^2)\mathcal{A} + 2(\mathcal{Z}_S - \mathcal{Z}_P)\mathcal{A}^2]\} \end{aligned} \tag{4.39}$$

$$\begin{aligned} N_f^2 \left\langle\!\left\langle (\bar{\sigma}_2)^3 \right\rangle\!\right\rangle_0^{(N_f)} &- 3N_f\,\langle\!\langle \sigma_4\bar{\sigma}_2 \rangle\!\rangle_0^{(N_f)} + \langle\!\langle \sigma_6 \rangle\!\rangle_0^{(N_f)} \\ &= \frac{V^3}{2N_f}[3\mathcal{Z}_S^2 V\Sigma^2 + 2(\mathcal{Z}_S^3 - \mathcal{Z}_P^3)] \end{aligned} \tag{4.40}$$

The large-volume behaviour of these combinations is particularly sensitive to the condensate Σ and to its fluctuation described by $\mathcal{Z}_S$ (Zweig-rule violation in the scalar channel). Both these parameters are precisely expected to be strongly affected by the vicinity of the critical point.

D. Positivity conditions

$(\bar{\sigma}_2)^2$, σ_4 and σ_6 are by definition positive, and their average over any topological sector should be positive as well. For $N_f \ll n_{\mathrm{crit}}(N_c)$, this positivity is trivially satisfied by the asymptotic behaviours predicted by the Leutwyler-Smilga sum rules (3.12)-(3.14).

When N_f is near (and below) $n_{\mathrm{crit}}(N_c)$, the volume dependence of the positive inverse moments is expressed through the sum rules of the previous section. They were derived at the leading order, for $\nu = 0$, and are functions of ζ, $\bar{S} = \mathcal{Z}_S/A$ and $\bar{P} = \mathcal{Z}_P/A$. The positivity of $\langle\!\langle (\bar{\sigma}_2)^2 \rangle\!\rangle_0^{(N_f)}$, $\langle\!\langle \sigma_4 \rangle\!\rangle_0^{(N_f)}$ and $\langle\!\langle \sigma_6 \rangle\!\rangle_0^{(N_f)}$ puts therefore constraints on the low-energy constants of $\tilde{\mathcal{L}}_2$.

In the plane $(\bar{S}, \bar{P})$, it is instructive to draw the domain where each of these sum rules is positive for any value of $\zeta = V\Sigma^2/\mathcal{A}$: we demand the positivity of a polynomial of second or third degree in ζ, whose coefficients are functions of $\bar{S}$ and $\bar{P}$ (and N_f). For a given number of flavours, this procedure excludes some values of $(\bar{S},\bar{P})$, which constitute the hatched areas on Figs. 4-7. If $\langle\!\langle(\bar{\sigma}_2)^2\rangle\!\rangle_0^{(N_f)}$ does not constrain $\bar{S}$ and $\bar{P}$ very much (Fig. 4), the positivity of $\langle\!\langle\sigma_4\rangle\!\rangle_0^{(N_f)}$ (Fig. 5) and $\langle\!\langle\sigma_6\rangle\!\rangle_0^{(N_f)}$ (Fig. 6) leads to stronger conditions. If N_f increases, the excluded domains broaden, as shown on Fig. 7, compared to Fig. 5. If we suppose that $N_f = 3$ is already near the critical point $n_{\rm crit}(N_c)$, and if we fix $\bar{P} = -1/2$ from the Gell-Mann–Okubo formula, the positivity of $\langle\!\langle\sigma_4\rangle\!\rangle_0^{(N_f)}$ yields the condition $\bar{S} \geq 1/6$, explaining the zero in the plot of R on Fig. 1, where the parameters $\bar{S}$ and $\bar{P}$ have been chosen on borderline of the positivity domain of $\langle\!\langle\sigma_4\rangle\!\rangle_0^{(N_f)}$.

Obviously, these areas are obtained through the leading-order approximation to the sum rules: the border of these domains is altered by subleading corrections, which should become large for small volumes. Furthermore, the pseudo-Goldstone bosons do not dominate the partition function if the box becomes smaller than $1/\Lambda_{QCD}$. To sum up, when we want the leading order of the sum rules to be positive for any ζ, we demand too much, and the resulting area is only an approximation of the really allowed domain in the plane $(\bar{S},\bar{P})$.

Furthermore, these positivity plots are only relevant for a number of flavour $N_f \sim n_{\rm crit}(N_c)$. Above the phase transition, $\langle\!\langle(\bar{\sigma}_2)^2\rangle\!\rangle_0^{(N_f)}$, $\langle\!\langle\sigma_4\rangle\!\rangle_0^{(N_f)}$ and $\langle\!\langle\sigma_6\rangle\!\rangle_0^{(N_f)}$ are still positive, but their large-volume behaviour is related in a different way to the low-energy constants of the effective Lagrangian, as described in Sec. III C. The positivity conditions stemming from the asymptotic behaviour of $\langle\!\langle(\bar{\sigma}_2)^2\rangle\!\rangle_0^{(N_f)}$ and $\langle\!\langle\sigma_6\rangle\!\rangle_0^{(N_f)}$ are satisfied for any $\bar{S}$ and $\bar{P}$. The only non-trivial relation is due to the sum rule (3.17) for $\langle\!\langle\sigma_4\rangle\!\rangle_0^{(N_f)}$ and reads:

$$(\bar{S}+\bar{P}-N_f)^2 + 2(\bar{S}-\bar{P})^2 \geq N_f^2 - 1. \tag{4.41}$$

To obtain this relation, we demand the infinite-volume limit of $\langle\!\langle\sigma_4\rangle\!\rangle_0^{(N_f)}$ to be positive. This limit is predicted by the sum rule (3.17) at the leading order. The subleading corrections to this sum rule vanish as $L \to \infty$ and they do not affect (4.41). On the contrary to the previous positivity conditions obtained near the critical point, (4.41) is therefore exact for $N_f > n_{\rm crit}(N_c)$.

V. SUBLEADING CORRECTIONS

This section is devoted to the next-to-leading contributions to the sum rules. In both phases, they behave as $1/L^2$ compared to the leading order considered so far.

A. $N_f \ll n_{\rm crit}(N_c)$

The Leutwyler-Smilga sum rules were obtained at the leading order of the effective Lagrangian $\mathcal{L}_2$ in the SχPT counting, restricted to the zero modes. The subleading corrections stem *a priori* from two sides: the non-zero modes (present already in $\mathcal{L}_2$), and the zero modes (beginning at the next-to-leading order $\mathcal{L}_4$). The first subleading corrections turn out to be of order $1/L^2$, and they come from the non-zero modes contributions to $\mathcal{L}_2$. They can be expressed as a (volume-dependent) renormalization of the quark condensate[6] in the sum rules (3.12)-(3.14).

The second type of subleading corrections arises from the zero-mode contribution to $\mathcal{L}_4$, quadratic in the quark mass matrix. This Lagrangian involves, among other terms, the counterterm $\langle M^\dagger M\rangle$ corresponding to the quadratic divergence of σ_2. Since the counting rule in this phase is $M \sim 1/V$, these quadratic terms are suppressed by a factor $1/L^4$ in comparison with the linear term in $\mathcal{L}_2$. Consequently, they appear as next-to-next-to-leading order contributions and will not be discussed here.

The non-zero modes arise in the decomposition of the Goldstone boson fields in Sec. III A:

$$U(x) = U_0 U_1(x) = U_0 \exp\left(i \sum_{a=1}^{N_f^2-1} \xi^a(x) t_a/F\right), \qquad \xi^a(x) = \sum_{n\neq 0} \phi_n^a \exp\left(i\frac{2\pi}{L} n\cdot x\right), \quad (5.1)$$

where n_μ is a four-vector whose components are integers ($n \neq 0$ means $\sum_\mu |n_\mu| \neq 0$). The unitarity of $U_1(x)$ leads to $\phi_{-n}^a = (\phi_n^a)^*$. The fluctuations of the non-zero modes are small, leading to the counting rule $\xi \sim \phi \sim \partial \sim 1/L$. The leading contribution for the non-zero modes is $\partial_\mu\xi\partial_\mu\xi$ and comes from the kinetic term of $\mathcal{L}_2$. It is counted with the same power as the leading term of the zero modes (3.7), but it can be directly integrated and becomes a simple contribution to the vacuum energy [27]. At the leading order, the zero modes are actually the only relevant degrees of freedom.

At the next-to-leading order, the corrections from the non-zero modes are due to the terms $\partial^2\xi^4$ and $M\xi^2$. They are only suppressed by a factor $1/L^2$ in comparison with the leading order $L^4 M$. The partition function (2.24) up to the next-to-leading order is finally:

$$\begin{aligned} Z_\nu = \mathcal{D}' \int_{\mathrm{U}(N_f)} [d\tilde{U}_0] (\det \tilde{U}_0)^\nu e^{-\mathcal{L}_{eff}(\tilde{U}_0, X)} & \int \prod_{n>0,a} d\phi_n^a \, d(\phi_n^a)^* \qquad (5.2) \\ \times \exp\left\{ -\frac{L^4}{4} \sum_{n\neq 0,a,b} (\phi_n^a)^* \left[\left(\frac{2\pi}{L}\right)^2 \frac{n^2}{2}\delta_{ab} + Q_{ab}\right] \phi_n^b - T_{4\phi} + O(L^{-4}) \right\}, \end{aligned}$$

where the condition $n > 0$ means: $n_0 > 0$, or $(n_0 = 0, n_1 > 0)$, or $(n_0 = n_1 = 0, n_2 > 0)$, or $(n_0 = n_1 = n_2 = 0, n_3 > 0)$. The $(N_f^2 - 1) \times (N_f^2 - 1)$ matrix arises:

$$Q_{ab} = \frac{\Sigma}{2F^2} \langle (t_a t_b + t_b t_a)(\tilde{U}_0^\dagger M + M^\dagger \tilde{U}_0)\rangle. \qquad (5.3)$$

$T_{4\phi}$ stands for the quartic term:

$$T_{4\phi} = \frac{2L^2\pi^2}{3F^2} \sum_{abcd,npqr\neq 0} \phi_n^a \phi_p^b \phi_q^c \phi_r^d \; n\cdot(q-p)\; \langle t_a t_b t_c t_d\rangle. \qquad (5.4)$$

In the integral over the non-zero modes in Eq. (5.2), these terms are suppressed by $1/L^2$ compared to the kinetic term.

---

[6] This result can be compared to the analysis performed in Ref. [30] concerning the finite size-effects arising in the effective description of a spontaneously broken $O(N)$-symmetry.

We begin with the term $T_{4\phi}$, which involves neither the quark mass matrix nor the zero-mode matrix $\tilde{U}_0$. We can treat it perturbatively to perform an expansion in powers of $1/L$, leading to:

$$\int \prod_{n>0,a} d\phi_n^a \; d(\phi_n^a)^* \tag{5.5}$$
$$\times \exp\left\{-\frac{L^4}{4}\sum_{n\neq 0,a,b}(\phi_n^a)^*\left[\left(\frac{2\pi}{L}\right)^2\frac{n^2}{2}\delta_{ab}+Q_{ab}\right]\phi_n^b\right\}(1-T_{4\phi}+\ldots).$$

We should now apply Wick's theorem and contract the fields ϕ in $T_{4\phi}$. We would use the propagator stemming from the kinetic term and the "mass term" Q_{ab}, where the latter is suppressed by $1/L^2$ compared to the first. But we want only the first subleading correction due to the tadpoles arising in $T_{4\phi}$. Since this correction is already $1/L^2$-suppressed compared to the leading order of the partition function, it can be calculated with propagators restricted to their momentum part (Q_{ab} would induce $1/L^4$-corrections). At the next-to-leading order, the contribution of $T_{4\phi}$ involves neither M, nor $\tilde{U}_0$ (which are only present in Q_{ab}): it is a global L-dependent term which can be factorized and eliminated by a redefinition of the normalization constant $\mathcal{D}'$.

Hence, the $1/L^2$-corrections are only due to the "mass term" Q_{ab} of the non-zero modes. The partition function restricted to a given topological sector becomes:

$$Z_\nu = \mathcal{D}''\int_{\mathrm{U}(N_f)}[d\tilde{U}_0](\det\tilde{U}_0)^\nu\exp(-\mathcal{L}_{eff}(\tilde{U}_0,X)) \quad \int\prod_{n>0,a}d\phi_n^a d(\phi_n^a)^* \tag{5.6}$$
$$\times\exp\left\{-\frac{L^4}{2}\sum_{n>0,a,b}(\phi_n^a)^*\left[\frac{1}{2}n^2\left(\frac{2\pi}{L}\right)^2\delta_{ab}+Q_{ab}\right]\phi_n^b+O(L^{-4})\right\}.$$

The Gaussian integral over $\{\phi^n\}$ can now be performed:

$$\mathcal{N}\prod_{n\neq 0}\exp\left[-\frac{L^2}{4\pi^2n^2}\mathrm{Tr}\;Q\right]=\mathcal{N}\exp\left[-\frac{L^2}{4\pi^2}\left(\sum_{n\neq 0}\frac{1}{n^2}\right)\mathrm{Tr}\;Q\right], \tag{5.7}$$

where $\mathcal{N}$ is an M-independent normalization factor. The trace over $a,b=1\ldots N_f^2-1$ leads to:

$$\mathrm{Tr}\;Q=\frac{N_f^2-1}{2N_f}\frac{\Sigma}{F^2}\langle M\tilde{U}_0^\dagger+\tilde{U}_0M^\dagger\rangle. \tag{5.8}$$

The integration over the non-zero modes ends up with the renormalization:

$$\Sigma(N_f)\to\Sigma(N_f)\left(1+g\frac{N_f^2-1}{2N_f}\right),\quad g=\frac{v}{2\pi^2F^2L^2},\quad v={\sum}'\frac{1}{n^2}. \tag{5.9}$$

If we include the first subleading corrections, the sum rules (3.12)-(3.14) remain therefore correct, provided that the parameters of the effective Lagrangian are renormalized, introducing an additional $1/L^2$-dependence related to the regularization scheme. In the dimensional regularization introduced by Hasenfratz and Leutwyler [30], the divergent sum v becomes $-4\pi^2\beta_1$, where β_1 is a "shape coefficient", related to the dimension and the geometry of the space-time. For a four-dimensional torus, $\beta_1 = 0.1405$ (see App. D for further comments).

In this case, the first subleading corrections to Eqs. (3.12)-(3.14) are summed up by the renormalization:

$$\Sigma(N_f) \to \Sigma_c(N_f) = \Sigma(N_f)\left(1 - \frac{N_f^2-1}{N_f}\cdot\frac{\beta_1}{F^2L^2}\right). \tag{5.10}$$

For instance, the relative correction $(\Sigma - \Sigma_c)/\Sigma$ remains smaller than α if the box size is greater than:

$$L_{\min} = \frac{1}{F}\sqrt{\frac{N_f^2-1}{N_f}\frac{\beta_1}{\alpha}}, \tag{5.11}$$

so that, for $N_f = 3$ flavours, the renormalization of Σ in the sum rules leads to a correction smaller than ten percent for box sizes larger than $1.9/F$ (in the case of the dimensional regularization).

B. Near the critical point

As before, two sources of subleading corrections should be taken into account: the non-zero modes from $\tilde{\mathcal{L}}_2$, Eq. (2.26), and the zero modes from the next-to-leading Lagrangian $\tilde{\mathcal{L}}_3$ [23]:

$$\begin{aligned}\tilde{\mathcal{L}}_3^{(N_f)} = \frac{1}{4}\{&\mathcal{X}(N_f)\langle\partial_\mu U^\dagger\partial_\mu U(M^\dagger U + U^\dagger M)\rangle \\ &+\tilde{\mathcal{X}}(N_f)\langle\partial_\mu U^\dagger\partial_\mu U\rangle\langle M^\dagger U + U^\dagger M\rangle \\ &-\mathcal{R}_1(N_f)\langle(M^\dagger U)^3 + (U^\dagger M)^3\rangle \\ &-\mathcal{R}_2(N_f)\langle(M^\dagger U + U^\dagger M)M^\dagger M\rangle \\ &-\mathcal{R}_3(N_f)\langle M^\dagger U - U^\dagger M\rangle\langle(M^\dagger U)^2 - (U^\dagger M)^2\rangle \\ &-\mathcal{R}_4(N_f)\langle(M^\dagger U)^2 + (U^\dagger M)^2\rangle\langle M^\dagger U + U^\dagger M\rangle \\ &-\mathcal{R}_5(N_f)\langle M^\dagger M\rangle\langle M^\dagger U + U^\dagger M\rangle \\ &-\mathcal{R}_6(N_f)\langle M^\dagger U - U^\dagger M\rangle^2\langle M^\dagger U + U^\dagger M\rangle \\ &-\mathcal{R}_7(N_f)\langle M^\dagger U + U^\dagger M\rangle^3\}.\end{aligned} \tag{5.12}$$

Since the counting rule is $ML^2 \sim 1$, both types of corrections are expected to contribute at the next-to-leading order $O(1/L^2)$, and could affect the previous quadratic or cubic volume-dependence of the sum rules.

The non-zero modes are explicitly defined by (5.1). Like in the standard counting, their leading term in the effective Lagrangian is the kinetic term $\partial_\mu\xi\partial_\mu\xi$, which is counted as $O(1/L^4)$. Its contribution (at the leading order) reduces to an overall constant, redefining the normalization of the partition function.

The next-to-leading contributions from the non-zero modes are of the form $B^aM^b\partial^c\xi^d$, with $2a+2b+c+d=6$, c and d even, and $c \leq d$. The possible terms are $BM\xi^2$, $M^2\xi^2$ and

$\partial^2\xi^4$ from $\tilde{\mathcal{L}}_2$, and $M\partial^2\xi^2$ from $\tilde{\mathcal{L}}_3$. At the next-to-leading order order, the path integral becomes:

$$Z_\nu = \mathcal{D}' \int_{\mathrm{U}(N_f)} [d\tilde{U}_0](\det \tilde{U}_0)^\nu \exp(-\mathcal{L}_{eff}(\tilde{U}_0, X)) \quad \int \prod_{n>0,a} d\phi_n^a \; d(\phi_n^a)^* \tag{5.13}$$
$$\times \exp\left\{ -\frac{L^4}{2} \sum_{n>0,a,b} (\phi_n^a)^* \left[n^2 \left(\frac{2\pi}{L}\right)^2 \left(\frac{1}{2}\delta_{ab} + \tilde{P}_{ab}\right) + \tilde{Q}_{ab} \right] \phi_n^b - T_{4\phi} + O\left(\frac{1}{L^4}\right) \right\},$$

with the $(N_f^2 - 1) \times (N_f^2 - 1)$ matrices:

$$\tilde{P}_{ab} = \frac{1}{2F^2} \left[\mathcal{X} \langle \{t_a, t_b\} (\tilde{U}_0^\dagger M + M^\dagger \tilde{U}_0) \rangle + \tilde{\mathcal{X}} \delta_{ab} \langle \tilde{U}_0^\dagger M + M^\dagger \tilde{U}_0 \rangle \right], \tag{5.14}$$

$$\begin{aligned} \tilde{Q}_{ab} = \frac{1}{F^2} \Bigg[& \frac{\Sigma}{2} \langle (t_a t_b + t_b t_a)(\tilde{U}_0^\dagger M + M^\dagger \tilde{U}_0) \rangle \\ & + \mathcal{A} \langle t_a \tilde{U}_0^\dagger M t_b \tilde{U}_0^\dagger M + t_a M^\dagger \tilde{U}_0 t_b M^\dagger \tilde{U}_0 \rangle \\ & + \mathcal{Z}_S \langle t_a (\tilde{U}_0^\dagger M - M^\dagger \tilde{U}_0) \rangle \langle t_b (\tilde{U}_0^\dagger M - M^\dagger \tilde{U}_0) \rangle \\ & + \mathcal{Z}_P \langle t_a (\tilde{U}_0^\dagger M + M^\dagger \tilde{U}_0) \rangle \langle t_b (\tilde{U}_0^\dagger M + M^\dagger \tilde{U}_0) \rangle \Bigg]. \end{aligned} \tag{5.15}$$

The quartic term $T_{4\phi}$ remains identical to its expression in the standard case (5.4) and it stems from the kinetic term of $\tilde{\mathcal{L}}_2$, whereas $\tilde{P}$ is due to $\tilde{\mathcal{L}}_3$ and $\tilde{Q}$ to the non-derivative part of $\tilde{\mathcal{L}}_2$. In Eq. (5.13), the contributions of these three terms are suppressed by $1/L^2$, compared to the kinetic term: $\pi^2 L^2 \sum_{n>0,a} n^2 |\phi_n^a|^2$.

For the same reasons as in the previous section, the integration of $T_{4\phi}$ leads at this order to a term independent of M and $\tilde{U}_0$, which merely redefines the overall normalization constant $\mathcal{D}$. At the next-to-leading order, the partition function for a given winding number reads:

$$Z_\nu = \mathcal{D}'' \int_{\mathrm{U}(N_f)} [d\tilde{U}_0](\det \tilde{U}_0)^\nu \exp(-\mathcal{L}_{eff}(\tilde{U}_0, X)) \quad \int \prod_{n>0,a} d\phi_n^a d(\phi_n^a)^* \tag{5.16}$$
$$\times \exp\left\{ -\frac{L^4}{2} \sum_{n>0,a,b} (\phi_n^a)^* \left[\frac{1}{2} n^2 \left(\frac{2\pi}{L}\right)^2 (\delta_{ab} + 2\tilde{P}_{ab}) + \tilde{Q}_{ab} \right] \phi_n^b \right\},$$

which yields after the integration over ϕ:

$$\begin{aligned} & \mathcal{N} \prod_{n\neq 0} \exp\left[-\mathrm{Tr}\ \tilde{P} - \frac{L^2}{4\pi^2 n^2} \mathrm{Tr}\ \tilde{Q} \right] \\ & = \mathcal{N} \exp\left[-\left(\sum_{n\neq 0} 1 \right) \mathrm{Tr}\ \tilde{P} - \frac{L^2}{4\pi^2} \left(\sum_{n\neq 0} \frac{1}{n^2} \right) \mathrm{Tr}\ \tilde{Q} \right], \end{aligned} \tag{5.17}$$

where $\mathcal{N}$ is an M- and $\tilde{U}_0$-independent normalization factor. The traces are taken over the indices $a, b = 1 \ldots N_f^2 - 1$:

$$\mathrm{Tr}\ \tilde{P} = \frac{1}{F^2L^2}\frac{N_f^2-1}{2N_f}(\mathcal{X} + N_f\tilde{\mathcal{X}})\langle X\tilde{U}_0^\dagger + \tilde{U}_0X^\dagger\rangle \tag{5.18}$$

$$\begin{aligned}\mathrm{Tr}\ \tilde{Q} = \frac{1}{2F^2L^4}\Bigg[&\Sigma L^2\frac{N_f^2-1}{N_f}\langle X\tilde{U}_0^\dagger + \tilde{U}_0X^\dagger\rangle + \left(\mathcal{A} - \frac{\mathcal{Z}_\mathcal{S}+\mathcal{Z}_\mathcal{P}}{N_f}\right)\left(\langle X\tilde{U}_0^\dagger\rangle^2 + \langle\tilde{U}_0X^\dagger\rangle^2\right)\\ &+\left(\mathcal{Z}_\mathcal{S}+\mathcal{Z}_\mathcal{P} - \frac{\mathcal{A}}{N}\right)\langle(X\tilde{U}_0^\dagger)^2 + (\tilde{U}_0X^\dagger)^2\rangle \qquad (5.19)\\ &+\frac{2(\mathcal{Z}_\mathcal{S}-\mathcal{Z}_\mathcal{P})}{N_f}\langle X\tilde{U}_0^\dagger\rangle\langle X^\dagger\tilde{U}_0\rangle - 2(\mathcal{Z}_\mathcal{S}-\mathcal{Z}_\mathcal{P})\langle X^\dagger X\rangle\Bigg],\end{aligned}$$

The integration over the non-zero modes ends up with a term of the same structure as $\tilde{\mathcal{L}}_2$, i.e. it renormalizes the parameters of the Lagrangian in the sum rules:

$$\Sigma(N_f) \to \Sigma(N_f) + g\frac{N_f^2-1}{2N_f}\Sigma(N_f) + \frac{2u}{F^2V}\frac{N_f^2-1}{2N_f}[\mathcal{X}(N_f) + N_f\tilde{\mathcal{X}}(N_f)], \tag{5.20}$$

$$\mathcal{A}(N_f) \to \mathcal{A}(N_f) + g\left[\mathcal{Z}_S(N_f) + \mathcal{Z}_P(N_f) - \frac{\mathcal{A}(N_f)}{N_f}\right], \tag{5.21}$$

$$\mathcal{Z}_S(N_f) \to \mathcal{Z}_S(N_f) + g\left[\frac{\mathcal{A}(N_f)}{2} - \frac{\mathcal{Z}_P(N_f)}{N_f}\right], \tag{5.22}$$

$$\mathcal{Z}_P(N_f) \to \mathcal{Z}_P(N_f) + g\left[\frac{\mathcal{A}(N_f)}{2} - \frac{\mathcal{Z}_S(N_f)}{N_f}\right], \tag{5.23}$$

$$\mathcal{H}(N_f) \to \mathcal{H}(N_f) - g\cdot 2[\mathcal{Z}_S(N_f) - \mathcal{Z}_P(N_f)], \tag{5.24}$$

with the sums to be regularized:

$$g = \frac{v}{2\pi^2F^2L^2}, \qquad v = {\sum}'\frac{1}{n^2}, \qquad u = {\sum}'1. \tag{5.25}$$

If we consider the dimensional regularization, we get $g = -2\beta_1/F^2L^2$ and $u = 0$ (see App. D).

With the counting $\Sigma L^2 \sim ML^2 \sim 1$, the first subleading corrections stem also from the zero modes in $\tilde{\mathcal{L}}_3$: they contain therefore the low-energy constants $\mathcal{R}_i$. If we consider the topological sector $\nu = 0$, the resulting corrections are quite simple to compute. When we expand Z_0 (restricted to the zero modes) as a polynomial X, the integrals with different powers of U and $U^\dagger$ vanish. In particular, the terms from $\tilde{\mathcal{L}}_3$ involve odd powers of the meson matrix and have to be combined with $\Sigma\langle X^\dagger U + U^\dagger X\rangle$. The resulting corrections are therefore $\Sigma\mathcal{R}_i$ and are counted as $O(1/L^2)$.

For $\nu = 0$ the final form of the sum rules, including the first subleading corrections, is:

$$\langle\!\langle(\bar{\sigma}_2)^2\rangle\!\rangle_0 = \frac{V^2\mathcal{A}^2}{16N_f^2(N_f^2-1)}\left[s_2^0 + s_2^\mathcal{R} + s_2^r\right], \tag{5.26}$$

$$\langle\!\langle\sigma_4\rangle\!\rangle_0 = \frac{V^2\mathcal{A}^2}{16N_f(N_f^2-1)}\left[s_4^0 + s_4^\mathcal{R} + s_4^r\right], \tag{5.27}$$

where s_k^0 is the leading term, already calculated in Sec. IV C, $s_k^\mathcal{R}$ collects the terms from the zero modes in $\tilde{\mathcal{L}}_3$, and s_k^r is due to the renormalization of $\tilde{\mathcal{L}}_2$ induced by the non-zero modes. The result is:

$$\begin{aligned} s_2^0 &= \zeta^2 + \zeta[4(2N_f^2+1)\bar{S} - 4\bar{P} - 4N_f] \\ &\quad +[4(2N_f^2+1)(\bar{S}^2+\bar{P}^2) - 8\bar{S}\bar{P} - 8N_f(\bar{S}+\bar{P}) + 4N_f^2], \end{aligned} \tag{5.28}$$

$$s_2^{\mathcal{R}} = \frac{\Sigma}{\mathcal{A}^2}[16N_f(\mathcal{R}_3 - \mathcal{R}_4) + 8N_f(N_f^2-1)\mathcal{R}_5 - 16N_f^2\mathcal{R}_6 + 48N_f^2\mathcal{R}_7], \tag{5.29}$$

$$\begin{aligned} s_2^r &= \frac{g}{N_f}\left\{2(N_f^2-1)\zeta^2 + \zeta[8N_f^2(N_f^2-1)\bar{S} - 16N_f^2\bar{P} + 8N_f] \right. \\ &\qquad +[-8(N_f^2-1)(\bar{S}^2+\bar{P}^2) - 16(3N_f^2+1)\bar{S}\bar{P} \\ &\qquad\quad \left. +16N_f(N_f^2+1)(\bar{S}+\bar{P}) - 16N_f^2]\right\} \\ &\quad +u\cdot 4\frac{N_f^2-1}{N_f}\frac{\Sigma(\mathcal{X}+N_f\tilde{\mathcal{X}})}{F^2\mathcal{A}}\left\{\zeta + 2\left[(2N_f^2+1)\bar{S} - \bar{P} - N_f\right]\right\}, \end{aligned} \tag{5.30}$$

and

$$\begin{aligned} s_4^0 &= \zeta^2 + \zeta[12\bar{S} - 4\bar{P} - 4N_f] \\ &\quad +[12\bar{S}^2 + 12\bar{P}^2 - 8\bar{S}\bar{P} - 8N_f\bar{S} - 8N_f\bar{P} + 4], \end{aligned} \tag{5.31}$$

$$s_4^{\mathcal{R}} = \frac{\Sigma}{\mathcal{A}^2}[-8(N_f^2-1)\mathcal{R}_2 + 16N_f\mathcal{R}_3 - 16N_f\mathcal{R}_4 - 16\mathcal{R}_6 + 48\mathcal{R}_7], \tag{5.32}$$

$$\begin{aligned} s_4^r &= \frac{g}{N_f}\left\{2(N_f^2-1)\zeta^2 + \zeta[8(N_f^2-1)\bar{S} - 8(N_f^2+1)\bar{P} - 4N_f(N_f^2-3)] \right. \\ &\qquad +[-8(N_f^2-1)(\bar{S}^2+\bar{P}^2) - 16(N_f^2+3)\bar{S}\bar{P} \\ &\qquad\quad \left. +32N_f(\bar{S}+\bar{P}) - 8(N_f^2+1)]\right\} \\ &\quad +u\cdot 4\frac{N_f^2-1}{N_f}\frac{\Sigma(\mathcal{X}+N_f\tilde{\mathcal{X}})}{F^2\mathcal{A}}\left\{\zeta + 2\left[3\bar{S} - \bar{P} - N_f\right]\right\}. \end{aligned} \tag{5.33}$$

It is worth commenting the above results: in the vicinity of the critical point, characterized by the counting $\Sigma L^2 \sim ML^2 \sim 1$, all the terms of the leading contribution s_k^0 are of the same order 1. $s_k^{\mathcal{R}}$ and s_k^r collect all the next-to-leading contributions, which are counted as $O(1/L^2)$. Consequently, for a fixed value of the condensate Σ, the inverse moments $\langle\!\langle(\bar{\sigma}_2)^2\rangle\!\rangle_0^{(N_f)}/V^2$ and $\langle\!\langle\sigma_4\rangle\!\rangle_0^{(N_f)}/V^2$ can be expressed in the form $\sum_{n=-1}^{4} a_n L^{2n}$. The even powers $n = 2, 4$ are the original leading terms, whereas the odd powers $n = -1, 1, 3$ arise from the next-to-leading corrections due to the non-zero modes. Hence, this type of correction does not mix with the leading contribution as far as the volume dependence is concerned.

This is not true for $s_k^{\mathcal{R}}$, which stems from the zero-mode contribution of $\tilde{\mathcal{L}}_3$. They modify the constant term $n = 0$ of the sum rules, and may be considered as small to the extent that Σ is small (let us recall that the dimensional estimate of the low-energy constants $\mathcal{R}_i$ leads to $\mathcal{R}_i \sim F^2/\Lambda_H$ with $\Lambda_H \sim 1$ GeV). Of course, close to the critical point, one precisely expects Σ to become small.

In the case of the λ^{-6}-sum rules (4.33)-(4.35), the situation is similar, but now, the constants $\mathcal{R}_i$ already affect the coefficient of ζ^1 in the sum rules (they also change the constant term ζ^0).

VI. EXTRACTION OF PARTICULAR LOW-ENERGY CONSTANTS

Near the critical point $n_{\rm crit}(N_c)$, we would like to exploit the sum rules for $\langle\!\langle(\bar\sigma_2)^2\rangle\!\rangle_0^{(N_f)}$ and $\langle\!\langle\sigma_4\rangle\!\rangle_0^{(N_f)}$ in order to isolate particular ratios of low-energy constants present in $\tilde{\mathcal{L}}_2$. In particular, it would be interesting to obtain a ratio with a specific sensitivity to the phase transition. To reach this goal, it is preferable to eliminate the next-to-leading corrections, which involve either unknown parameters like $\mathcal{R}_i$ or regularization-dependent quantities like g. As already pointed out, Eqs. (5.26) and (5.27) can be viewed as expansions in the variables ΣL^2 and ML^2. Hence, they are even functions of L.

A. Varying the size of the box

To exploit the structure of the sum rules at the next-to-leading order, it is therefore interesting to introduce the derivative-like operator:

$$\delta_a[F](L) = \frac{a^2}{8L\left(L^2-\frac{a^2}{4}\right)} \times\left\{\left(L-\frac{a}{2}\right)F(L+a)+\left(L+\frac{a}{2}\right)F(L-a)-2LF(L)\right\}, \tag{6.1}$$

where a is an arbitrary parameter. If we consider an even monomial $F(L)=L^{2k}$, $\delta^a[F]$ is an even polynomial of degree L^{2k-4}. We obtain for the first powers:

$$L^0 \to 0, \qquad L^2 \to 0, \qquad L^4 \to a^4, \tag{6.2}$$

$$L^6 \to a^4(3L^2+2a^2), \qquad L^8 \to a^4(6L^4+12L^2a^2+3a^2). \tag{6.3}$$

If we denote $t_2 = \langle\!\langle(\bar\sigma_2)^2\rangle\!\rangle_0^{(N_f)}/V^2$ and $t_4=\langle\!\langle\sigma_4\rangle\!\rangle_0^{(N_f)}/V^2$, we have:

$$\delta_a[N_f t_2 - t_4](L) = \frac{a^4}{2N_f}\Sigma^2\mathcal{Z}_S + O(1/L^6), \tag{6.4}$$

$$\delta_a[\delta_a[t_2]](L) = \frac{3a^8}{8N_f^2(N_f^2-1)}\Sigma^4 + O(1/L^{10}). \tag{6.5}$$

In order to get a quantity which is invariant with respect to the QCD renormalization group, we take the ratio of these two sum rules:

$$\rho = \frac{\delta_a[\delta_a[t_2]]}{\delta_a[N_f t_2 - t_4]}(L) = \frac{3a^4}{4N_f(N_f^2-1)}\cdot\frac{\Sigma^2}{\mathcal{Z}_S}+O(1/L^6). \tag{6.6}$$

The evaluation of ρ requires the knowledge of t_2 and t_4 for five different box sizes: $L-2a$, $L-a$, L, $L+a$, $L+2a$. Notice that a is not required to be large; it is sufficient to have $L-2a$ much bigger than $1/\Lambda_H$. On the other hand, for too small a, the difference operator δ_a may be too sensitive to numerical errors.

For a discretized torus (a lattice), we can put $L=na$ with n integer and a the lattice spacing. Eqs. (6.4)-(6.6) remain true, and the comparison of different volumes is translated into the evaluation of the inverse moments on lattices with the same spacing, but with various numbers of sites. The powers in the lattice spacing a on the right-hand side of Eqs. (6.4)-(6.6) reflect merely the dimension of the involved quantities.

Eqs. (6.4)-(6.6) are independent of the next-to-leading order contributions: this allows to consider smaller volumes than previously stated (for instance, the estimate $L > 1.9/F$ of Sec. V A, based on our next-to-leading order analysis does not necessarily apply to the sum rule (6.6)). The volume-independence of Eqs. (6.4)-(6.6) could already be seen for smaller volumes. Moreover, the inverse moments must fulfill another non-trivial consistency relation:

$$\rho' = \frac{\delta_a[\delta_a[t_2]]}{\delta_a[\delta_a[t_4]]}(L) = \frac{1}{N_f} + O(1/L^{10}). \tag{6.7}$$

The ratio ρ is invariant under the QCD renormalization group and its variations with N_f could reflect the proximity of the critical point in a particularly clean way, as discussed in the next section.

B. Relevance of the ratio $\mathcal{Z}_S/\Sigma^2$

We have argued in a previous paper [9] that the approach to $n_{\text{crit}}(N_c)$ could result into a large Zweig-rule violation in the scalar channel. Let us recall briefly the argument. We consider the chiral limit for the first N_f light flavours of common mass $m \to 0$, and denote by s the (N_f+1)-th quark, whose mass m_s is non-zero, but still considered as light compared to the scale of the theory (real QCD corresponds to $N_f = 2$). Here, we typically consider N_f such that $N_f + 1 < n_{\text{crit}}(N_c) \leq N_f + 2$. $\Sigma(N_f)$ is a function of m_s, with the derivative:

$$\frac{\partial}{\partial m_s}\Sigma(N_f) = \lim_{m\to 0}\int dx \langle \bar{u}u(x)\bar{s}s(0)\rangle^c \equiv \Pi_Z(m_s), \tag{6.8}$$

where the superscript c stands for the connected part. Since $\Sigma(N_f) \to \Sigma(N_f+1)$ for $m_s \to 0$, one can write:

$$\Sigma(N_f) = \Sigma(N_f+1) + \int_0^{m_s} d\mu\ \Pi_Z(\mu) = \Sigma(N_f+1) + m_s Z_{\text{eff}}(m_s) + O(m_s^2 \log m_s), \tag{6.9}$$

where $Z_{\text{eff}}(m_s)$, defined in Ref. [9], is essentially $2\mathcal{Z}_S(N_f+1)$, up to corrections of the order $(\Sigma(N_f+1))^2$, which are small in the vicinity of the critical point. Close to $n_{\text{crit}}(N_c)$, the condensate term need not dominate the expansion (6.9) in powers of m_s, due to the suppression of $\Sigma(N_f+1)$. The large variation of the quark condensate from N_f to N_f+1 is then reflected by a large value of $\mathcal{Z}_S(N_f+1)$, related to the Zweig-rule violation in the 0^{++} channel. Once expressed through the Dirac spectrum, Σ can be interpreted as the average density of small eigenvalues, whereas Π_Z is related to the density-density correlation. The ratio $\mathcal{Z}_S/\Sigma^2$ measures therefore the fluctuation of the quark condensate. For N_f near the critical point $n_{\text{crit}}(N_c)$ where Σ vanishes, one may expect a suppression of Σ and an enhancement of its fluctuations $\mathcal{Z}_S$.

We can express the ratio $\mathcal{Z}_S/\Sigma^2$ by introducing the Gell-Mann–Oakes–Renner ratio [31], measuring the condensate in physical units:

$$X_{\mathrm{GOR}}(N_f) = \frac{2m\Sigma(N_f)}{F_\pi^2 M_\pi^2}, \tag{6.10}$$

where m denotes the common mass of the N_f lightest quarks ($m = (m_u + m_d)/2$ for $N_f = 2$). Following the analysis of Ref. [9], one obtains from Eq. (6.9), in the approximation $Z_{\mathrm{eff}} \sim 2\mathcal{Z}_S$:

$$\frac{F_\pi^4 \mathcal{Z}_S(N_f+1)}{\Sigma^2(N_f+1)} \sim \frac{F_\pi^4 Z_{\mathrm{eff}}}{2\Sigma^2(N_f+1)} \tag{6.11}$$

$$= \frac{X_{\mathrm{GOR}}(N_f) - X_{\mathrm{GOR}}(N_f+1)}{[X_{\mathrm{GOR}}(N_f+1)]^2} \cdot \frac{F_\pi^2}{2rM_\pi^2} + \ldots, \tag{6.12}$$

where r stands for m_s/m and the dots denote higher-order terms. For $N_f \ll n_{\mathrm{crit}}(N_c)$, the right-hand side of Eq. (6.12) is very small. It can be illustrated by choosing $N_f = 2$, $X(2) \sim 0.9$ and $r \sim 26$ (Standard χPT estimates). The difference of the GOR ratios satisfies in this case the lower bound: $X(2) - X(3) > 0.2$ [10,20], and we consider this bound conservatively as an equality. In this case, the right-hand side of Eq. (6.12) is of the order of 10^{-2} (let us notice that in this case, this quantity is related to $16L_6(\mu)$ at a typical hadronic scale $\mu \sim M_\rho$, c.f. Ref. [20]). The proximity of a phase transition could be detected by a considerable increase of the ratio (6.11) compared to its typical size $\sim 10^{-2}$.

C. Application to the lattice

An evaluation of the inverse moments through lattice simulation represents a few interesting features. We work at finite volumes: the volume dependence is crucial to obtain information on the relevant low-energy constants of the effective Lagrangian, and the extrapolation to an infinite volume is avoided. The limitation to the topologically trivial sector is natural on the lattice by choosing strictly periodic boundary conditions.

We do not aim at solving full QCD on the lattice. We want to compute Dirac inverse moments, averaged over the gluonic configurations with the statistical weight (2.13). To perform this more limited task, we have to know the Dirac spectrum for each gluonic configuration. It can be obtained through the square of the Dirac operator: $\not{D}^2 = D^2 + iF^{\mu\nu}\sigma_{\mu\nu}$. It seems much simpler to discretize this operator instead of $\not{D}$ itself. In particular, the doubling problems are not expected to arise in the spectrum of an elliptic operator like D^2. It should be stressed that, while this procedure could be applied in our particular problem, it can hardly represent a general solution for doubling in the spectrum of lattice fermions.

For a given gluonic configuration, we can therefore compute the inverse moments from the Dirac spectrum (which is independent of the number of flavours). The essential contribution to each inverse moments stems from the lowest eigenvalues. In this case, the N_f-dependence in the average $\langle\!\langle\rangle\!\rangle_0^{(N_f)}$ is expected to arise mainly through the N_f-th power of the product of the lowest Dirac eigenvalues, i.e. from the infrared part of the truncated fermion determinant, c.f. Eq. (2.19). The ultraviolet part of the determinant should then be included by a matching with the perturbative tail as discussed in Ref. [32]. A first possibility consists in generating the gluonic configurations in the quenched approximation, and to include explicitly the fermion determinant in the observable. The advantage of this method is that it would allow to change easily and continuously N_f while keeping the same set of gluonic configurations. On the other hand, Monte-Carlo simulation of the pure gauge theory could lead to a rather different distribution of small Dirac eigenvalues than a simulation including the fermion determinant into the statistical weight: the quenched generation of the configurations may therefore lead to biased results, when we use these configurations to compute quantities including explicitly a fermion determinant as an observable. If this reweighting procedure turns out to be inefficient, the generation of the gluonic configurations would have to include the product of the lowest Dirac eigenvalues in the statistical weight. The configurations should be regenerated for each value of N_f.

The computation of the ratio ρ seems particularly attractive on the lattice. We have to compare five different lattice sizes to calculate this ratio, invariant under the QCD renormalization group and protected from next-to-leading order effects. When N_f increases, an enhancement of $1/\rho$ would clearly indicate the vicinity of the critical point $n_{\rm crit}(N_c)$ where the condensate vanishes.

VII. CONCLUSION

Two descriptions of Euclidean QCD on a torus can be fruitfully matched : the first involves the spectrum of the Dirac operator whereas the second relies on the effective theory of Goldstone bosons. The spontaneous breakdown of chiral symmetry can be related to the large-volume behaviour of inverse moments of the Dirac eigenvalues, $\sum_{n>0} 1/\lambda_n^k$, averaged over topological sets of gluonic configurations. Because of their sensitivity to N_f, these inverse moments can be used to detect chiral phase transitions occurring when the number of massless flavours increases.

The quark condensate $\Sigma(N_f)$ is the chiral order parameter that is the most sensitive to N_f. It is conceivable that just above the first critical point $n_{\rm crit}(N_c)$ where Σ vanishes, the chiral symmetry is only partially restored. Below this critical point, the large-volume behaviour of the inverse spectral moments is given by the Leutwyler-Smilga sum rules (3.12)-(3.14) and it is driven by the quark condensate (this behaviour corresponds to eigenvalues accumulating as $1/L^4$). Above $n_{\rm crit}(N_c)$, the asymptotic volume dependence of the inverse moments changes (see Eqs. (3.16)-(3.17)), corresponding to eigenvalues behaving as $1/L^2$. In this case, the dominant contribution comes from terms in the effective Lagrangian quadratic in quark masses.

When N_f increases and approaches $n_{\rm crit}(N_c)$, the quark condensate becomes small, and its fluctuations (related to the Zweig-rule violation in the scalar channel) are expected to become large: the terms of the effective Lagrangian linear and quadratic in the quark masses may therefore contribute with a comparable magnitude. Hence, it may become necessary to include both of them into the leading order of the expansion of $\mathcal{L}_{\rm eff}$, in order to derive the large-volume behaviour of the inverse spectral moments, which interpolates between both phases. The resulting sum rules have been analyzed in the topologically trivial sector $\nu = 0$ (see Eqs. (4.31)-(4.35)). In particular, the formulae concerning positive inverse moments restrict the parameters of the effective Lagrangian.

For $N_f \ll n_{\rm crit}(N_c)$, the first subleading corrections to Leutwyler-Smilga sum rules are due to the non-zero modes, and reduce to a volume-dependent redefinition of the low-energy constant Σ. The next-to-leading corrections to these formulae have been calculated also for

N_f close to the critical point $n_{\rm crit}(N_c)$. The part arising from non-zero modes is translated into a redefinition of the low-energy constants Σ, $\mathcal{Z}_S$, $\mathcal{Z}_P$ and $\mathcal{A}$. The NLO contribution due to zero modes can be computed directly for $\nu = 0$. All NLO corrections behave as $O(L^{-2})$ relatively to the leading contribution.

We have shown that combining inverse spectral moments at different volumes allows one to isolate the ratio of low-energy constants $\mathcal{Z}_S/\Sigma^2$ which is particularly sensitive to the chiral phase transition. The resulting "five-volume formula" (6.6) is furthermore insensitive to NLO finite-size corrections, and it is invariant under the QCD renormalization group.

The study of the inverse spectral moments of the Dirac operator seems a promising tool to investigate chiral phase transitions in association with lattice simulations. The sums over eigenvalues can be computed from a set of gluonic configurations with $\nu = 0$ and the corresponding Dirac spectra, obtained after the diagonalization of $D^2 + F\sigma/2$. The N_f-dependence is explicit, via the infrared part of the truncated fermion determinant and the finite-volume effects are not only taken into account, but essential for our purposes.

The possibility to vary on the lattice parameters fixed in the real world, like N_f (and N_c) could open a new window on the chiral structure of QCD vacuum. This investigation could lead to a better understanding of QCD-like theories in general. For instance, among electroweak symmetry breaking models, technicolor and similar proposals have often been ruled out, assuming a smooth and simple dependence on N_f and N_c leading to a direct link with actual QCD phenomenology [33]. If the chiral phase structure of vector-like confining gauge theories turned out to be richer, the chiral symmetry could be broken following a different pattern from actual QCD, offering new possibilities for technicolor-like models [34]. The study of N_f-induced chiral phase transitions could therefore represent a step towards alternative theories of electroweak symmetry breaking.

APPENDIX A: INTEGRATION OVER UNITARY MATRICES

In the flavour space, we can define a complete set $\{t_a\}$ of N_f^2 Hermitian $N_f \times N_f$ matrices generating $\mathrm{U}(N_f)$. a is an index from 0 to $N_f^2 - 1$: t_0 is proportional to the identity, and the other matrices are traceless. They are normalized by:

$$\langle t_a t_b \rangle = \frac{1}{2}\delta_{ab}, \qquad \sum_a t_a t_a = \frac{1}{2} N_f, \tag{A1}$$

with the interesting identities for any matrices A and B:

$$\sum_a \langle t_a A \rangle \langle t_a B \rangle = \frac{1}{2}\langle AB \rangle, \tag{A2}$$

$$\sum_a t_a A t_a = \frac{1}{2}\langle A \rangle, \qquad \sum_a \langle t_a A t_a B \rangle = \frac{1}{2}\langle A \rangle\langle B \rangle. \tag{A3}$$

We can decompose any complex matrix on this basis: $X = \sum_a X_a t_a$. If we want to perform integrations over $\mathrm{U}(N_f)$ involving a unitary matrix U, the non-vanishing integrals have as many components from $U = \sum_a U_a t_a$ as from $U^\dagger = \sum_a U_a^* t_a$. The first ones are:

$$\int_{\mathrm{U}(N_f)} [dU] = 1, \tag{A4}$$

$$\int_{\mathrm{U}(N_f)} [dU] U_a U_b^* = \frac{2}{N_f}\delta_{ab}, \tag{A5}$$

$$\begin{aligned}\int_{\mathrm{U}(N_f)} [dU] U_a U_b^* U_c U_d^* = &\frac{4}{N_f^2-1}(\delta_{ab}\delta_{cd} + \delta_{ad}\delta_{bc}) \\ &-\frac{16}{N_f(N_f^2-1)}\langle t_a t_b t_c t_d + t_a t_d t_c t_b\rangle,\end{aligned} \tag{A6}$$

$$\begin{aligned}\int_{\mathrm{U}(N_f)} [dU] U_a U_b^* U_c U_d^* U_e U_f^* = &\frac{8}{N_f(N_f^2-1)(N_f^2-4)} \\ &\times\Big\{(N_f^2-2)[\delta_{ab}\delta_{cd}\delta_{ef} + \delta_{ab}\delta_{cf}\delta_{ed} + \delta_{ad}\delta_{cb}\delta_{ef} \\ &\qquad +\delta_{ad}\delta_{cf}\delta_{eb} + \delta_{af}\delta_{cb}\delta_{ed} + \delta_{af}\delta_{cd}\delta_{eb}] \\ &-4N_f[\delta_{ab}\langle t_c t_d t_e t_f + t_c t_f t_e t_d\rangle + \delta_{ad}\langle t_b t_c t_f t_e + t_b t_e t_f t_c\rangle \\ &\quad +\delta_{af}\langle t_b t_c t_d t_e + t_b t_e t_d t_c\rangle + \delta_{cb}\langle t_a t_d t_e t_f + t_a t_f t_e t_d\rangle \\ &\quad +\delta_{cd}\langle t_a t_b t_e t_f + t_a t_f t_e t_b\rangle + \delta_{cf}\langle t_a t_b t_e t_d + t_a t_d t_e t_b\rangle \\ &\quad +\delta_{eb}\langle t_a t_d t_c t_f + t_a t_f t_c t_d\rangle + \delta_{ed}\langle t_a t_b t_c t_f + t_a t_f t_c t_b\rangle \\ &\quad +\delta_{ef}\langle t_a t_b t_c t_d + t_a t_d t_c t_b\rangle] \\ &+16\langle t_a t_b t_c t_d t_e t_f + t_a t_b t_e t_d t_c t_f + t_a t_b t_e t_f t_c t_d + t_a t_b t_c t_f t_e t_d \\ &\quad +t_a t_d t_c t_b t_e t_f + t_a t_d t_e t_b t_c t_f + t_a t_d t_e t_f t_c t_b + t_a t_d t_c t_f t_e t_b \\ &\quad +t_a t_f t_c t_d t_e t_b + t_a t_f t_e t_d t_c t_b + t_a t_f t_e t_b t_c t_d + t_a t_f t_c t_b t_e t_d\rangle\Big\}.\end{aligned} \tag{A7}$$

APPENDIX B: LEADING-ORDER GENERALIZED LAGRANGIAN FOR TWO FLAVOURS

For $N_f = 2$, the situation is slightly different from the generic case, because SU(2) representations are pseudoreal. In particular, the correlator $\langle(\bar{u}u)(\bar{d}d)\rangle$, which defines $\mathcal{Z}_S^{(2)}$, contains a determinant-like invariant and is no more an order parameter. The leading order of the generalized Lagrangian for SU(2) is [35]:

$$\begin{aligned}\tilde{\mathcal{L}}_2^{(2)} = \frac{1}{4}\{&F^2(2)\langle\partial_\mu U^\dagger \partial_\mu U\rangle - 2\Sigma(2)\langle U^\dagger M + M^\dagger U\rangle \\ &-\mathcal{A}(2)\langle(U^\dagger M)^2 + (M^\dagger U)^2\rangle - \mathcal{Z}_P(2)\langle U^\dagger M - M^\dagger U\rangle^2 \\ &-\mathcal{H}(2)\langle M^\dagger M\rangle - \mathcal{H}'(2)(\det M + \det M^\dagger)\}\,.\end{aligned} \tag{B1}$$

The new counterterm $\mathcal{H}'(2)$ is consistently counted $O(p^2)$ in GχPT, since $\det M$ involves two powers of the mass.

Despite similarities between $\mathcal{H}'(2)$ and $\mathcal{H}(2)$ (terms with no mesonic fields, absent from the low-energy processes), $\mathcal{H}'(2)$ is not necessarily divergent. In the Minkowskian metric, it can be defined through the chiral limit of the Zweig-suppressed correlator:

$$2i\int d^4x\ e^{ipx}\langle 0|T\{\bar{u}u(x)\bar{d}d(0)\}|0\rangle = \mathcal{H}'^r(2)(\mu) + O(p^2)_{\mathrm{G}\chi\mathrm{PT}}. \tag{B2}$$

It is easy to prove that, in the chiral limit, the identity operator, the quark condensate and the gluon condensate do not contribute to the Operator Product Expansion of $\langle(\bar{u}u)(\bar{d}d)\rangle$ [7], The correlator (B2) is dominated by $d=6$ operators and it behaves as $O(1/p^4)$ for large momenta. It is therefore superconvergent. $\mathcal{H}'(2)$ can be related to the scalar spectrum through a dispersion relation with no subtraction, similarly as in Ref. [20]. Despite the difficulty of estimating the resulting integral, $\mathcal{H}'(2)$ can be determined in principle from experimental data in the 0^+ sector, including not only the low-energy dynamics, but also information about higher resonances.

Since $\mathcal{H}'(2)$ is free of ultraviolet divergences, we can formally rewrite the GχPT leading order of the two-flavour Lagrangian in the generic form ($N_f \geq 3$). We use the identity, true for any 2×2 matrix C: $\langle C\rangle^2 - \langle C^2\rangle = 2\det C$. This leads to a formal identification:

$$\mathcal{A}(N_f) \leftrightarrow \mathcal{A}(2) - \mathcal{H}'(2)/2, \qquad \mathcal{Z}_S(N_f) \leftrightarrow \mathcal{H}'(2)/4, \tag{B3}$$

$$\mathcal{Z}_P(N_f) \leftrightarrow \mathcal{Z}_P(2) + \mathcal{H}'(2)/4, \qquad \mathcal{H}(N_f) \leftrightarrow \mathcal{H}(2), \tag{B4}$$

which enables us to treat the two-flavour Lagrangian in the same framework as the generic case, even though the phenomenological interpretation of its parameters is different.

APPENDIX C: EXPANSION COEFFICIENTS OF THE PARTITION FUNCTION

This section is devoted to the calculation of the coefficients arising when the partition function is expanded in powers of $X = ML^2$ for N_f near (but under) the critical point $n_{\mathrm{crit}}(N_c)$. The main lines of the computation are exposed in Sec. IV B, but its technical details and the results for an arbitrary winding number are presented here. The coefficients α_ν, β_ν... are defined in Eq. (4.8).

1. Leading coefficient α_ν

To compute $\alpha_\nu(b,z,a)$, we begin with $\alpha_\nu(b,0,a)$, given by the leading order in x of the group integral:

$$I_\nu^\alpha = I_\nu(b,a;x\cdot 1) = \int_{\mathrm{U}(N_f)} [dU](\det U)^\nu \exp[bx\langle U^\dagger\rangle + ax^2\langle U^{\dagger 2}\rangle]. \tag{C1}$$

---

[7] Basically, the quark condensate cannot appear in OPE of (B2) without a mass term, vanishing in the chiral limit, whereas the discrete symmetry $u_L \to -u_L$ rules out the identity operator and the gluon condensate. We thank B. Moussallam for this remark.

We can use Weyl's formula to transform the group integral into an integration over the eigenvalues of U: $\exp(i\phi_k)$ $(k = 1 \ldots N_f)$:

$$\int_{\mathrm{U}(N_f)} [dU] \to \frac{1}{N_f!} \int \left(\prod_{k=1}^{N_f} \frac{d\phi_k}{2\pi} \right) |P|^2, \tag{C2}$$

with $P = \prod_{k<l} \left(e^{i\phi_k} - e^{i\phi_l} \right)$. P is a linear combination of $\exp(i \sum n_k \phi_k)$, with n_k integers, antisymmetric under the exchange of two angles, so that for $k \neq l$, n_k and n_l must be different. Their set forms one of the $N_f!$ permutations of $(0, 1, 2 \ldots N_f - 1)$, and P collects all of them, with a sign depending on the signature of the permutation. If the integrand is symmetric under the angle permutations, PP^* can be rewritten [21]:

$$|P|^2 = N_f! \sum_{\sigma \in \mathcal{P}(N_f)} \epsilon(\sigma) \exp \left[i \sum_{k=1}^{N_f} (\sigma(k) - k) \phi_k \right], \tag{C3}$$

with $\mathcal{P}(N_f)$ the set of the permutations over $(1 \ldots N_f)$ and ϵ the signature.

The group integral I_ν^α becomes:

$$I_\nu^\alpha = \frac{1}{N_f!} \int \left(\prod_{k=1}^{N_f} \frac{d\phi_k}{2\pi} \right) |P|^2 \prod_{k=1}^{N_f} \left(e^{i\nu\phi_k} \exp \left[bxe^{-i\phi_k} + ax^2 e^{-2i\phi_k} \right] \right). \tag{C4}$$

When $|P|^2$ is replaced by its symmetrized value (C3), the integrals over the angles become independent of each other:

$$I_\nu^\alpha = \sum_{\sigma \in \mathcal{P}(N_f)} \epsilon(\sigma) \prod_{k=1}^{N_f} \int \frac{d\phi_k}{2\pi} e^{i(k - \sigma(k) + \nu)\phi_k} \exp \left[bxe^{-i\phi_k} + ax^2 e^{-2i\phi_k} \right] \tag{C5}$$

$$= \sum_{\sigma \in \mathcal{P}(N_f)} \epsilon(\sigma) \prod_{k=1}^{N_f} x^{s(k)} \sum_{\substack{p_k + 2q_k = s(k) \\ p_k, q_k \geq 0}} \frac{1}{p_k! q_k!} b^{p_k} a^{q_k}, \tag{C6}$$

with $s(k) = k - \sigma(k) + \nu$. Obviously, if $s(k) < 0$ for at least one k, the permutation does not contribute. But $\mathcal{P}(N_f)$ includes the identical permutation and $\nu \geq 0$: there is at least one contributing term in I_ν^α, and all these contributions lead actually to the same leading power in x:

$$\prod_{k=1}^{N_f} x^{s(k)} = x^{\sum k - \sigma(k) + \nu} = x^{\nu N_f}, \tag{C7}$$

which is consistent with the factor $(\det X)^\nu$ in the expansion (4.8). We get therefore:

$$\alpha_\nu(b, z = 0, a) = \sum_{m = 0 \ldots \nu N_f / 2} b^{\nu N_f - 2m} a^m c_m, \tag{C8}$$

with the purely combinatorial coefficients:

$$c_m = \sum_{\sigma\in\mathcal{P}(N_f)} \epsilon(\sigma) \sum_{\substack{\{q_k=1\ldots s(k)/2\} \\ \sum q_k=m}} \left[\prod_k q_k!(s(k)-2q_k)!\right]^{-1}. \tag{C9}$$

Another way to describe c_m is the generating polynomial:

$$\sum_{m=0\ldots\nu N_f/2} w^m c_m = \begin{vmatrix} X_\nu & X_{\nu+1} & X_{\nu+2} & \cdots & X_{\nu+N-1} \\ X_{\nu-1} & X_\nu & X_{\nu+1} & \cdots & X_{\nu+N-2} \\ X_{\nu-2} & X_{\nu-1} & X_\nu & \cdots & X_{\nu+N-3} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ X_{\nu-N+1} & X_{\nu-N+2} & X_{\nu-N+3} & \cdots & X_\nu \end{vmatrix}, \tag{C10}$$

with the polynomials in w:

$$X_j = \sum_{q=0\ldots j/2} \frac{w^q}{q!(j-2q)!}. \tag{C11}$$

Since the derivatives of I_ν with respect to b and z are not independent, Eq. (4.7) yields the general expression of α_ν:

$$\alpha_\nu(b,z,a) = \sum_{l+2m+2p=\nu N_f} b^l a^m z^p \frac{(l+2p)!}{l!p!} c_m. \tag{C12}$$

2. Subleading coefficients β_ν, γ_ν, δ_ν

We denote the various derivatives of α_ν:

$$\alpha'_\nu = \frac{\partial\alpha_\nu}{\partial b} \qquad \dot{\alpha}_\nu = \frac{\partial\alpha_\nu}{\partial a} \qquad \alpha''_\nu = \frac{\partial^2\alpha_\nu}{\partial b^2} = \frac{\partial\alpha_\nu}{\partial z} \tag{C13}$$

For $b=\bar{b}$, $a=\bar{a}$, $z=\bar{z}$, for N flavours, and denoting $K=N+|\nu|$, the coefficients are:

$$\beta = \alpha\frac{1}{K}(y+b^2) + \alpha'\frac{1}{KN}b\,(2Nz+2a+Ny) + \alpha''\frac{2}{NK}y(Nz+a) \tag{C14}$$

$$\begin{aligned}\gamma = \alpha&\left\{\frac{1}{K^2-1}[\frac{b^4}{2}+2b^2y+2b^2z+y^2+2z^2+2a^2]\right. \\ &\left.-\frac{1}{K(K^2-1)}2a[b^2+2z]+\frac{(K-N)(KN+1)}{K(K^2-1)(N^2-1)}2a^2\right\} \\ +\alpha'&\left\{\frac{1}{K^2-1}b[b^2y+2b^2z+2y^2+6yz+4z^2]\right. \\ &-\frac{1}{K(K^2-1)}2ab[y+2z]+\frac{1}{N(K^2-1)}2ab[b^2+2y+2z]\end{aligned} \tag{C15}$$

$$

\end{aligned}
\tag{C16}
$$

$$-\frac{K+N}{NK(K^2-1)(N^2-1)}2a^2y^2\Big\}$$

$$+\frac{KN+1}{NK(K^2-1)(N^2-1)}\left[\dot{\alpha}2a^2(2z+b^2)+\dot{\alpha}'4a^2by+\dot{\alpha}''2a^2y^2\right]$$

APPENDIX D: DIMENSIONAL REGULARIZATION ON A TORUS

Following the regularization procedure described by Hasenfratz and Leutwyler [30], we want to regularize sums like:

$$G_H=\frac{1}{V}\sum_p H(p), \tag{D1}$$

where H is a function and p is summed over $2\pi/L\cdot\mathbb{Z}^4$. The Fourier transform of $H(p)$ is:

$$\tilde{H}(x)=\int\frac{d^dp}{(2\pi)^d}e^{ipx}H(p), \tag{D2}$$

and fulfills the identity:

$$G_H=\frac{1}{V}\sum_p H(p)=\sum_l \tilde{H}(l), \tag{D3}$$

where l is summed over $L\cdot Z^4$. Because of the relation:

$$\lim_{V\to\infty}G_H=\lim_{V\to\infty}\frac{1}{V}\sum_p H(p)=\int\frac{d^dp}{(2\pi)^d}H(p)=\tilde{H}(0), \tag{D4}$$

it is possible to separate in G_H the cut-off and the volume dependences:

$$G_H=\lim_{V\to\infty}G_H+g_H, \qquad\qquad g_H={\sum_l}'\tilde{H}(l). \tag{D5}$$

The infinite-volume limit of G_H contains the divergences for $d\to 4$ and has to be regularized, whereas g_H depends only on the volume.

For $v=\sum' 1/n^2$, we have the relations:

$$\frac{1}{V}{\sum_p}'\frac{1}{p^2}=\lim_{M\to 0}\left[\frac{1}{V}\sum_p\frac{1}{p^2+M^2}-\frac{1}{VM^2}\right]=\lim_{M\to 0}\left[G_H-\frac{1}{VM^2}\right]. \tag{D6}$$

with $H(p)=1/(p^2+M^2)$. In the case of the dimensional regularization, (D5) involves:

$$G_H=\frac{M^2}{8\pi^2}(\ln M+c_1)+g_H, \qquad g_H=\frac{1}{VM^2}-\frac{\beta_1}{L^2}+O(M^2), \tag{D7}$$

where c_1 contains a pole for $d=4$, and β_1 is a constant called "shape coefficient", depending on the geometry of the box. For a four-dimensional torus, $\beta_1=0.1405$. The dimensional regularization yields finally:

$$v = \sum_{n \neq 0} \frac{1}{n^2} \leftrightarrow -4\pi^2 \beta_1 \tag{D8}$$

For u, we can follow the same guideline and take $H(p) = 1$ for $p \neq 0$ and $H(0) = 0$. Its Fourier transform is $\tilde{H}(l) = \delta^{(4)}(l)$. g_H vanishes, and we know that dimensionally regularized integrals like $\int \frac{d^d p}{(2\pi)^d}$ vanish as well, so that:

$$u = \sum_{n \neq 0} 1 \leftrightarrow 0. \tag{D9}$$

FIGURES

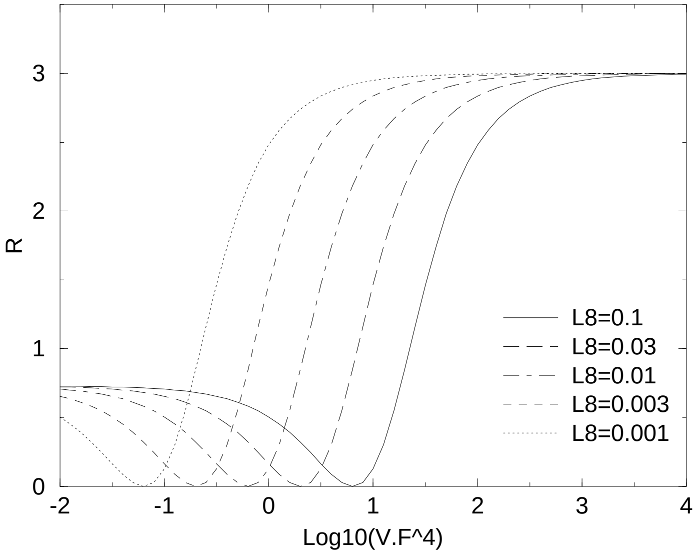

FIG. 1. Variations of $R = \langle\langle \sigma_4 \rangle\rangle_0 / \langle\langle (\bar{\sigma}_2)^2 \rangle\rangle_0$ as a function of the volume, measured in physical units F_π^{-4} ($N_f = 3$ flavours, $\mathcal{Z}_P/\mathcal{A} = -1/2$ and $\mathcal{Z}_S/\mathcal{A} = 1/6$). The variation of $\hat{L}_8$ is only a redefinition of the scaling parameter ζ and leads to a global shift of the curves. The vanishing for intermediate volumes is commented in Sec. IV D.

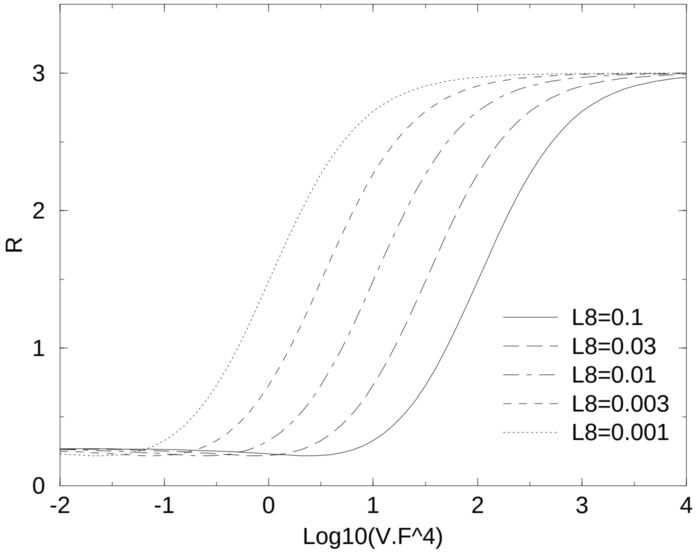

FIG. 2. Variations of $R = \langle\langle \sigma_4 \rangle\rangle_0 / \langle\langle (\bar{\sigma}_2)^2 \rangle\rangle_0$ as a function of the volume, measured in physical units F_π^{-4} ($N_f = 3$ flavours, $\mathcal{Z}_P/\mathcal{A} = -1/2$ and $\mathcal{Z}_S/\mathcal{A} = 1$).

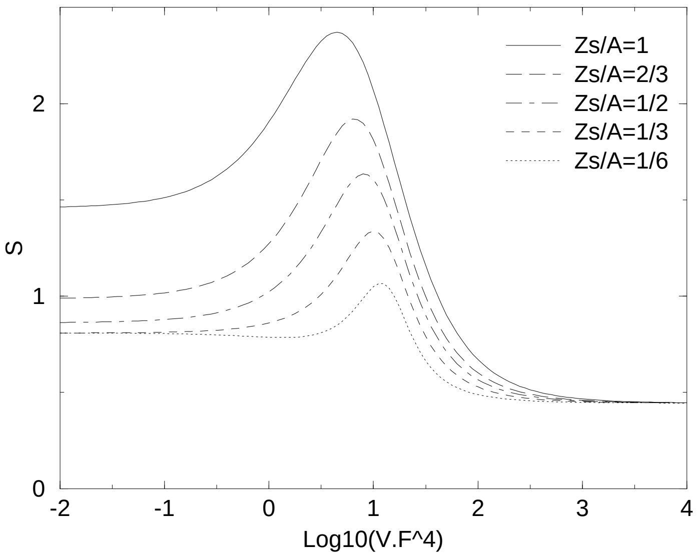

FIG. 3. Variations of $S = \langle\langle(\bar{\sigma}_2)^3\rangle\rangle_0/\langle\langle\sigma_6\rangle\rangle_0$ as a function of the volume measured in physical units F_π^{-4}, for different values of $\bar{S} = \mathcal{Z}_S/\mathcal{A}$ ($N_f = 3$, $\hat{L}_8 = 0.1$, $\bar{P} = -1/2$). S is sensitive to the parameter $\bar{S}$ even for intermediate volumes. A different value of $\hat{L}_8$ would merely lead to a global shift of the curves.

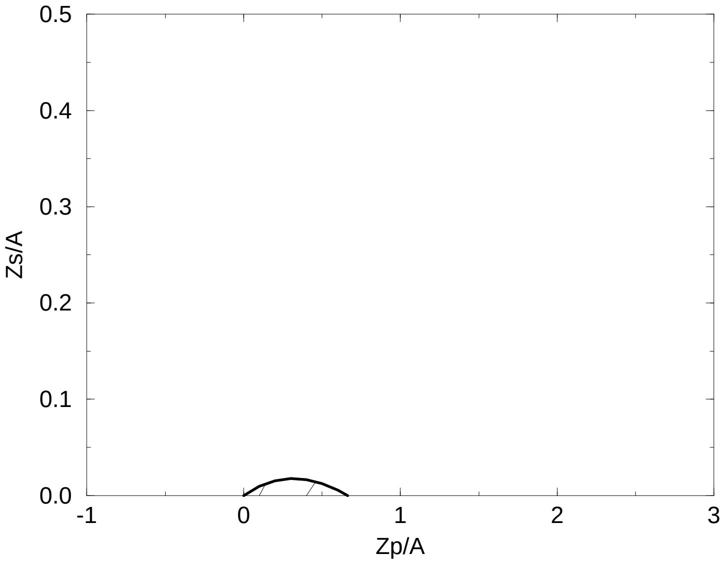

FIG. 4. Values of $(\mathcal{Z}_S/\mathcal{A}, \mathcal{Z}_P/\mathcal{A})$ for which the sum rule (4.31) for $\left\langle\left\langle(\bar{\sigma}_2)^2\right\rangle\right\rangle_0^{(N_f=3)}$ is positive for any positive scaling parameter $\zeta = V\Sigma^2/\mathcal{A}$ (the forbidden zone is hatched).

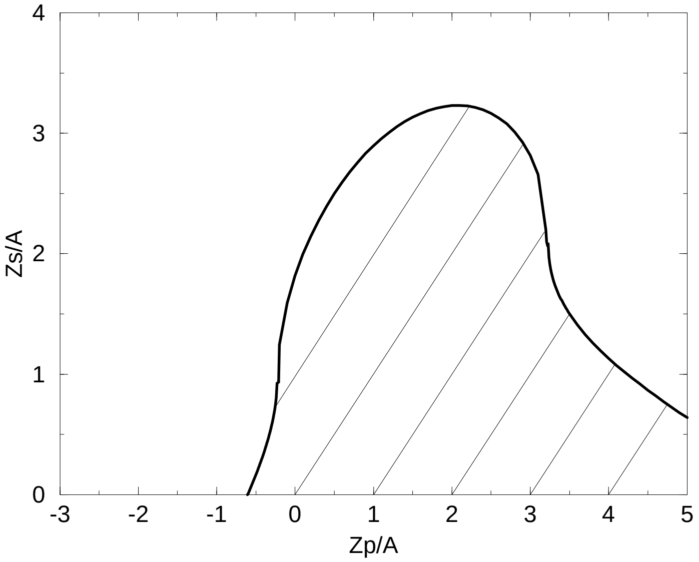

FIG. 5. Values of $(\mathcal{Z}_S/\mathcal{A}, \mathcal{Z}_P/\mathcal{A})$, for which the sum rule (4.32) for $\langle\!\langle \sigma_4 \rangle\!\rangle_0^{(N_f=3)}$ is positive for any positive scaling parameter $\zeta = V\Sigma^2/\mathcal{A}$ (the forbidden zone is hatched).

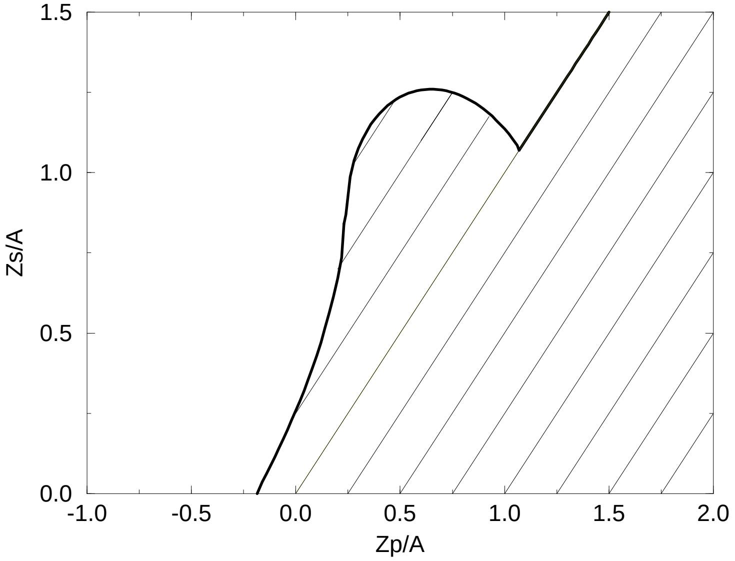

FIG. 6. Values of $(\mathcal{Z}_S/\mathcal{A}, \mathcal{Z}_P/\mathcal{A})$, for which the sum rule (4.33) for $\langle\!\langle \sigma_6 \rangle\!\rangle_0^{(N_f=3)}$ is positive for any positive scaling parameter $\zeta = V\Sigma^2/\mathcal{A}$ (the forbidden zone is hatched).

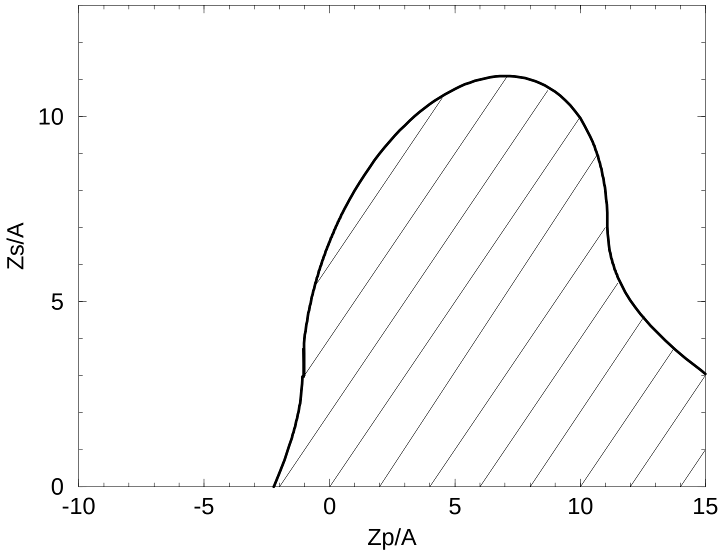

FIG. 7. Values of $(\mathcal{Z}_S/\mathcal{A}, \mathcal{Z}_P/\mathcal{A})$ for which the sum rule (4.32) for $\langle\langle\sigma_4\rangle\rangle_0^{(N_f=10)}$ is positive for any positive scaling parameter $\zeta = V\Sigma^2/\mathcal{A}$ (the forbidden zone is hatched).
